
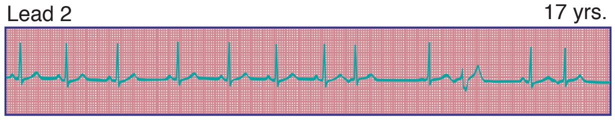

Figure 435-3 Premature atrial contraction (PAC). QRS complexes—the 8th, 10th, and final—in this strip are preceded by a P wave that is inverted, indicative of an ectopic origin of atrial depolarization. Note that the 8th and final QRS complexes resemble those of sinus origin, whereas the 10th is aberrantly conducted. This shift in origin is a function of the preceding cycle length, which influences the refractory period of the bundle branches. The fact that the pause after the PAC is longer than 2 P-P intervals implies that the premature atrial depolarization has invaded and discharged the sinus node and then reset it so that it fires later.

Figure 435-4 Premature ventricular contractions in a bigeminal rhythm, in a patient who is hyperventilating. Note that the premature beat is wide and has a completely different morphology from that of the sinus beat. The premature beat is not preceded by a discernable premature P wave or any appreciable deformation of the preceding T wave.

It is important to distinguish PVCs that are benign from those that are likely to lead to more severe arrhythmias. The former usually disappear during the tachycardia of exercise. If they persist or become more frequent during exercise, the arrhythmia may have greater significance. The following criteria are indications for further investigation of PVCs that could require **suppressive therapy:** (1) 2 or more ventricular premature beats in a row; (2) multiform PVCs; (3) increased ventricular ectopic activity with exercise; (4) R-on-T phenomenon (premature ventricular depolarization occurs on the T wave of the preceding beat); (5) extreme frequency of beats (e.g., >20% of total beats on Holter monitoring); and (6) most importantly, the presence of underlying heart disease, a history of heart surgery, or both. The best therapy for benign PVCs is reassurance that the arrhythmia is not life threatening, although very symptomatic individuals may benefit from suppressive therapy. Malignant PVCs are usually secondary to another medical problem (electrolyte imbalance, hypoxia, drug toxicity, or cardiac injury). Successful treatment includes correction of the underlying abnormality. An intravenous lidocaine bolus and drip is the first line of therapy, with more effective drugs such as amiodarone reserved for refractory cases or for patients underlying ventricular dysfunction or hemodynamic compromise.

435.3 Supraventricular Tachycardia

George F. Van Hare

Supraventricular tachycardia (SVT) is a general term that includes essentially all forms of paroxysmal or incessant tachycardia except ventricular tachycardia. The category of SVT can be divided into 3 major subcategories: reentrant tachycardias using an accessory pathway, reentrant tachycardias without an accessory pathway, and ectopic or automatic tachycardias. Atrioventricular reciprocating tachycardia (AVRT) involves an accessory pathway and is the most common mechanism of SVT in infants. Atrioventricular node reentry tachycardia (AVNRT) is rare in infancy but there is an increasing incidence of AVNRT in childhood and into adolescence. Atrial flutter is rarely seen in children with normal hearts, whereas intraatrial reentry tachycardia also known as atrial flutter, is common in patients following cardiac surgery. Atrial and junctional ectopic tachycardias are more commonly associated with abnormal hearts (cardiomyopathy) and in the immediate postoperative period following surgery for congenital heart disease.

CLINICAL MANIFESTATIONS

Reentrant SVT is characterized by an abrupt onset and cessation; it may occur when the patient is at rest or exercising, and in infants it may be precipitated by an acute infection. Attacks may last only a few seconds or may persist for hours. The heart rate usually exceeds 180 beats/min and may occasionally be as rapid as 300 beats/min. The only complaint may be awareness of the rapid heart rate. Many children tolerate these episodes extremely well, and it is unlikely that short paroxysms are a danger to life. If the rate is exceptionally rapid or if the attack is prolonged, precordial discomfort and heart failure may occur. In children, SVT may be exacerbated by exposure to nonprescription decongestants or by bronchodilators.

In young infants, the diagnosis may be more obscure because of the inability to communicate their symptoms. The heart rate at this age is normally higher than in older children and it increases greatly with crying. Infants with SVT on occasion initially present with heart failure, because the tachycardia may go unrecognized for a long time. The heart rate during episodes is frequently in the range of 240-300 beats/min. If the attack lasts 6-24 hr or more, heart failure may be recognized, and the infant will have an ashen color, and be restless and irritable, with tachypnea, poor pulses and hepatomegaly. When tachycardia occurs in the fetus, it can cause hydrops fetalis, which is the in utero manifestation of heart failure.

In neonates, SVT is usually manifested as a narrow QRS complex (<0.08 sec). The P wave is visible on a standard electrocardiogram in only 50-60% of neonates with SVT, but it is detectable with a transesophageal lead in most patients. **Differentiation from sinus tachycardia** may be difficult, but is important, as sinus tachycardia requires treatment of the underlying problem (e.g., sepsis, hypovolemia) rather than antiarrhythmic medication. If the rate is >230 beats/min with an abnormal P-wave axis (a normal P wave is positive in leads I and aVF), sinus tachycardia is not likely. The heart rate in SVT also tends to be *relatively unvarying*, whereas in sinus tachycardia the heart rate *varies* with changes in vagal and sympathetic tone. AV reciprocating tachycardia uses a bypass tract that may either be able to conduct bidirectionally **(Wolff-Parkinson-White [WPW] syndrome)** or retrograde only **(concealed accessory pathway)**. Patients with WPW syndrome have a small, but real risk of sudden death. If the accessory pathway rapidly conducts in antegrade fashion, the patient is at risk for atrial fibrillation begetting ventricular fibrillation. Risk stratification, including 24 hr Holter monitoring and exercise study, may help differentiate patients at higher risk for sudden death from WPW. Syncope is an ominous symptom in WPW and any patient with syncope and WPW syndrome should have an electrophysiology study and likely catheter ablation.

The typical electrocardiographic features of the WPW syndrome are seen when the patient is not having tachycardia. These features include a short P-R interval and slow upstroke of the QRS (delta wave) (Fig. 435-5). Although most often present in patients with a normal heart, this syndrome may also be associated with Ebstein anomaly of the tricuspid valve, or hypertrophic cardiomyopathy. The critical anatomic structure is an accessory pathway consisting of a muscular bridge connecting atrium to ventricle on either the right or the left side of the AV ring (Fig. 435-6). During sinus rhythm, the impulse is carried over both the AV node and the accessory pathway; it produces some degree of fusion of the 2 depolarization fronts that results in an abnormal QRS. During AVRT, an impulse is carried in antegrade fashion through the AV node **(orthodromic tachycardia),** which results in a normal QRS complex, and in retrograde fashion

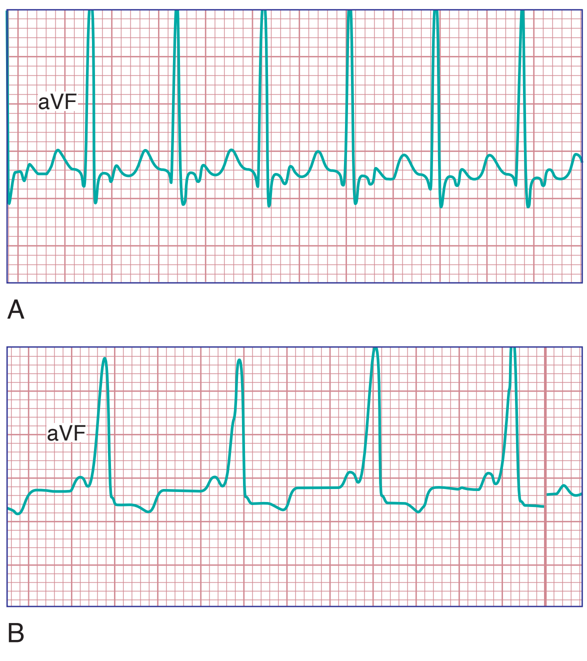

Figure 435-5 **A,** Supraventricular tachycardia in a child with Wolff-Parkinson-White (WPW) syndrome. Note the normal QRS complexes during the tachycardia, as well as clear retrograde P waves seen on the upstroke of the T waves. **B,** Later, the typical features of WPW syndrome are apparent (short P-R interval, delta wave, and wide QRS).

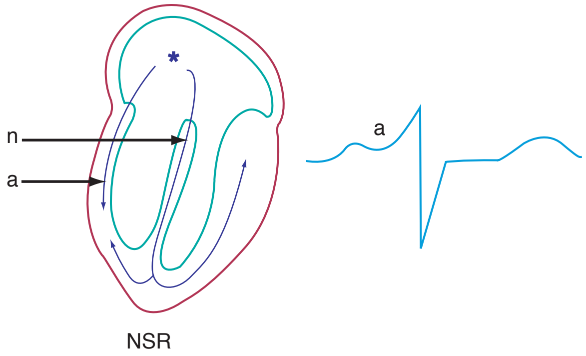

Figure 435-6 Schematic representation of the heart with a right-sided accessory pathway (Wolff-Parkinson-White syndrome). The *asterisk* indicates initiation of the sinus beat. The *arrows* indicate the direction and spread of excitation. The electrocardiographic complex shown represents a fusion beat that combines activation over the normal *(n)* and accessory *(a)* pathways. The latter inscribes the delta wave. NSR, normal sinus rhythm.

through the accessory pathway to the atrium, thereby perpetuating the tachycardia. In these cases, only after cessation of the tachycardia is the typical ECG features of WPW syndrome recognized (see Fig. 435-5). When rapid antegrade conduction occurs through the accessory pathway during tachycardia and the retrograde re-entry pathway to the atrium is via the AV node **(antidromic tachycardia),** the QRS complexes are wide and the potential for more serious arrhythmias (ventricular fibrillation) is greater, especially if atrial fibrillation occurs.

AVNRT involves the use of 2 pathways within the AV node, so-called *slow* and *fast* AV node pathways. This arrhythmia is more commonly seen in adolescence. It is one of the few forms of SVT that is occasionally associated with syncope. This arrhythmia is often seen in association with exercise.

TREATMENT

Vagal stimulation by placing of the face in ice water (in older children) or by placing an ice bag over the face (in infants) may abort the attack. To terminate the attack, older children may be taught vagal maneuvers such as the Valsalva maneuver, straining, breath holding, or standing on their head. Ocular pressure must never be performed, and carotid sinus massage is very rarely effective. When these measures fail, several pharmacologic alternatives are available (see Table 435-1). In stable patients, adenosine by rapid intravenous push is the **treatment of choice** because of its rapid onset of action and minimal effects on cardiac contractility. The dose may need to be increased if no effect on the tachycardia is seen. Because of the potential for adenosine to initiate atrial fibrillation, it should never be administered without a means for direct current (DC) cardioversion near at hand. Calcium channel blockers such as verapamil have also been used in the initial treatment of SVT in older children. Verapamil may reduce cardiac output and produce hypotension and cardiac arrest in infants younger than 1 yr; it is, therefore, contraindicated in this age group. In urgent situations when symptoms of severe heart failure have already occurred, synchronized DC cardioversion (0.5-2 J/kg) is recommended as the initial management (see Chapter 67).

Once the patient has been converted to sinus rhythm, a longer-acting agent may is selected for maintenance therapy. In patients without an antegrade accessory pathway (non-WPW), the β-blockers are the mainstay of drug therapy. Digoxin is also popular and may be effective in infants, but less so in older children. In children with WPW, digoxin or calcium channel blockers may increase the rate of antegrade conduction of impulses through the bypass tract, with the possibility of ventricular fibrillation, and are therefore contraindicated. These patients are usually managed with β-blockers. In patients with resistant tachycardias, flecainide, propafenone, sotalol, and amiodarone have all been used. Most antiarrhythmic agents have the potential of causing new dangerous arrhythmias (**proarrhythmia**) and decreasing heart function. Flecainide and propafenone in particular should be limited to use in patients with otherwise normal hearts.

If cardiac failure occurs because of prolonged tachycardia in an infant with a normal heart, cardiac function usually returns to normal after sinus rhythm is reinstituted, although it may take days to weeks. Infants with SVT diagnosed within the 1st 3-4 mo of life have a lower incidence of recurrence than do those in whom it is initially diagnosed at a later age. These patients have an 80% chance of resolution by the 1st yr of life, although approximately 30% will have recurrences later in childhood; if medical therapy is required, it can be tapered within a year and the patient watched for signs of recurrence. Parents should be taught to measure the heart rate in their infants, so that prolonged unapparent episodes of SVT may be detected before heart failure occurs.

Twenty-four hour electrocardiographic (Holter) recordings are useful in monitoring the course of therapy and in detecting brief runs of asymptomatic tachycardia, particularly in younger children and infants. Some centers use **transesophageal pacing** to evaluate the effects of therapy in infants. More detailed electrophysiologic studies performed in the cardiac catheterization laboratory are often indicated in patients with refractory SVTs who are candidates for **catheter ablation**. During an electrophysiologic study, multiple electrode catheters are placed transvenously in different locations in the heart. Pacing is performed to evaluate the conduction characteristics of the accessory pathway and to initiate the tachyarrhythmia, and mapping is performed to locate the accessory pathway. **Catheter ablation** of an accessory pathway is frequently used in children and teenagers, as well as in patients who require multiple agents or find drug side effects intolerable or for whom arrhythmia control is poor. Ablation may be performed either by radiofrequency ablation, which creates tissue heating, or cryoablation, in which tissue is frozen (Fig. 435-7). The overall initial success rate for catheter ablation ranges from approximately 90-98%, depending on the location of the accessory pathway. Surgical ablation of bypass tracts is only rarely done, and is proposed only in carefully selected patients.

The management of SVT caused by **AVNRT** is nearly identical to that for AVRT. Children with AVNRT are not at increased risk of sudden death, as they do not have a manifest accessory pathway. In practice, their episodes are more likely to be brought on by exercise or other forms of stress, and the heart rates can be quite fast, leading to chest pain, dizziness, and, occasionally, syncope. If chronic antiarrhythmic medication is desired, β-blockers are the drugs of choice; acutely, AVNRT responds to adenosine. Less is known about the natural history, but patients with AVNRT are seen quite commonly in adulthood, so spontaneous resolution seems unlikely. Patients are quite amenable to catheter ablation, either using radiofrequency energy or cryoablation, with high success rates and low complication rates.

Atrial ectopic tachycardia is an uncommon tachycardia in childhood. It is characterized by a variable rate (seldom >200 beats/min), identifiable P waves with an abnormal axis, and either a sustained or incessant nonsustained tachycardia. This form of atrial tachycardia has a single automatic focus. Identification of this mechanism is aided by monitoring the electrocardiogram while initiating vagal or pharmacologic therapy. Reentry tachycardias "break" suddenly, whereas automatic tachycardias gradually slow down and then gradually speed up again. Atrial ectopic tachycardias are usually more difficult to control pharmacologically than are the more common reentrant tachycardias. If pharmacologic therapy with a single agent is unsuccessful, catheter ablation is suggested and has a success rate >90%.

Chaotic or multifocal atrial tachycardia is defined as atrial tachycardia with ≥3 ectopic P waves, frequent blocked P waves, and varying P-R intervals of conducted beats. This arrhythmia occurs most often in infants younger than 1 yr, usually without cardiac disease, although some evidence suggests an association with viral myocarditis or pulmonary disease. The goal of drug treatment is slowing of

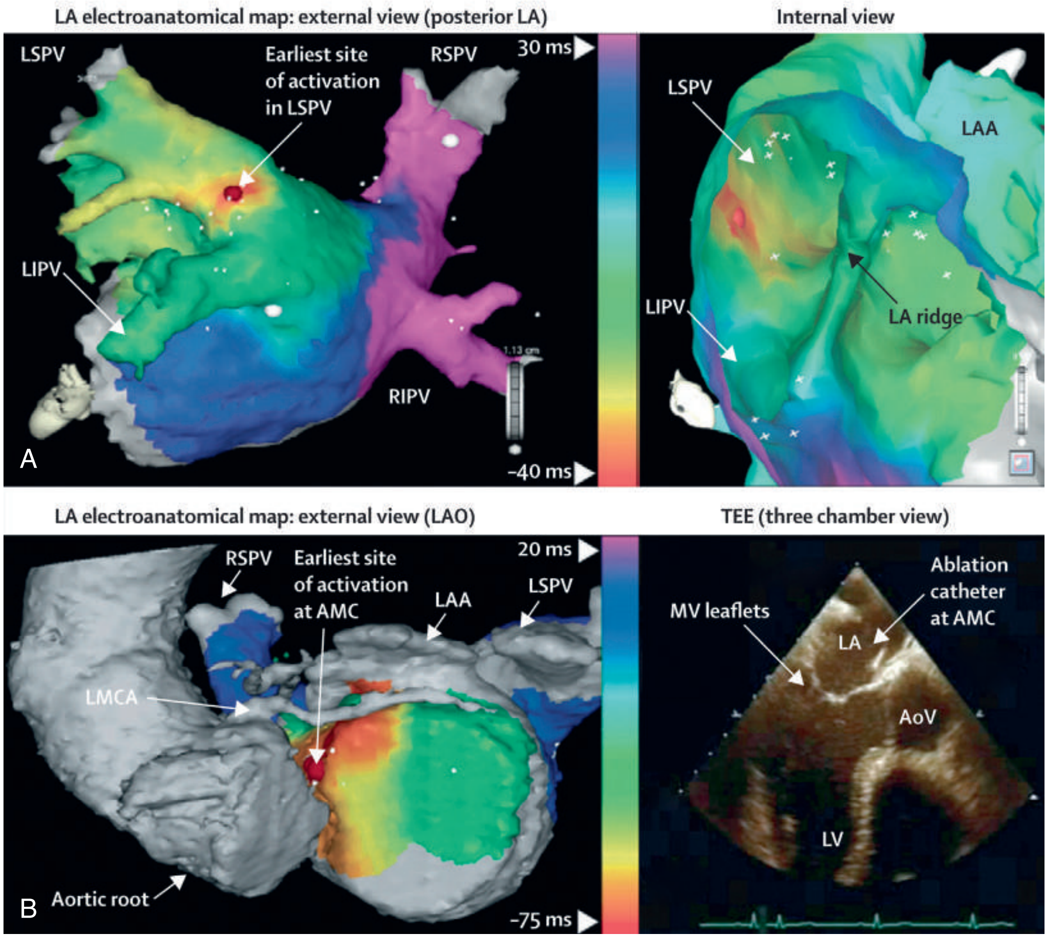

Figure 435-7 Three-dimensional electroanatomical mapping of focal atrial tachycardias. Focal site of early activation *(red)* is shown, with radial propagation away from that central site. The activation map was superimposed onto the patient's cardiac CT scan, taken the day before the procedure and imported into the mapping system. **A,** Earliest site of activation, mapped to the posterior aspect of the LSPV ostium. Posterior external view *(left side)* and endoluminal or internal view looking from within the left atrium into the mouth of the LSPV *(right side)* are shown. **B,** Earliest site mapped to the aortomitral continuity. The anatomic relation between the mitral annulus and the aortic root can be clearly appreciated *(left side)*. The location of the ablation catheter at the site of earliest atrial activation during atrial tachycardia is shown on the TEE image *(right side)*. AMC, aortomitral continuity; AoV, aortic valve; LA, left atrium; LAA, left atrial appendage; LAO, left anterior oblique; LIPV, left inferior pulmonary veins; LMCA, left main coronary artery; LSPV, left superior pulmonary vein; LV, left ventricle; MV, mitral valve; RIPV, right inferior pulmonary veins; RSPV, right superior pulmonary vein; TEE, transesophageal echocardiogram. *(From Lee G, Sanders P, Kalman JM: Catheter ablation of atrial arrhythmias: state of the art.* Lancet *380:1509–1518, 2012, Fig 3.)*

the ventricular rate, as conversion to sinus may not be possible, and multiple agents are often required. When this arrhythmia occurs in infancy, it usually terminates spontaneously by 3 yr of age.

Accelerated junctional ectopic tachycardia (JET) is an automatic (non-reentry) arrhythmia in which the junctional rate exceeds that of the sinus node and AV dissociation results. This arrhythmia is most often recognized in the early postoperative period after cardiac surgery and may be extremely difficult to control. Reduction of the infusion rate of catecholamines and control of fever are important adjuncts to management. Congenital JET may be seen in the absence of surgery. It is incessant, and can lead to dilated cardiomyopathy. Intravenous amiodarone is effective in the treatment of postoperative JET. Patients who require chronic therapy may respond to amiodarone or sotalol. Congenital JET can be cured by catheter ablation, but long-term AV block requiring a pacemaker is a prominent complication.

Atrial flutter, also known as *intraatrial reentrant tachycardia,* is an atrial tachycardia characterized by atrial activity at a rate of 250-300 beats/min in children and adolescents, and 400-600 beats/min in neonates. The mechanism of common atrial flutter consists of a reentrant or rhythm originating in the right atrium circling the tricuspid valve annulus. Because the AV node cannot transmit such rapid impulses, some degree of **AV block** is virtually always present, and the ventricles respond to every 2nd to 4th atrial beat (Fig. 435-8). Occasionally, the response is variable and the rhythm appears irregular.

In older children, atrial flutter usually occurs in the setting of congenital heart disease; neonates with atrial flutter frequently have normal hearts. Atrial flutter may occur during acute infectious illnesses but is most often seen in patients with large stretched atria, such as those associated with long-standing mitral or tricuspid insufficiency, tricuspid atresia, Ebstein anomaly, or rheumatic mitral stenosis. Atrial flutter can also occur after palliative or corrective intra-atrial surgery. Uncontrolled atrial flutter may precipitate heart failure. Vagal maneuvers or adenosine may produce a temporary slowing of the heart rate as a result of increased AV block, allowing a diagnosis to be made. The **diagnosis** is confirmed by electrocardiography, which demonstrates the rapid and regular atrial sawtoothed flutter waves. Atrial flutter usually converts immediately to sinus rhythm by **synchronized DC cardioversion,** which is most often the **treatment of choice.** Patients with chronic atrial flutter in the setting of congenital heart disease may be at increased risk for **thromboembolism** and stroke and should thus undergo anticoagulation before elective cardioversion. β-blockers or calcium channel blockers may be used to slow the ventricular response

in atrial flutter by prolonging the AV node refractory period. Other agents may be used to maintain sinus rhythm, and choices include Class I agents such as procainamide or propafenone, Class III agents such as amiodarone and sotalol. Catheter ablation has been used in patients with normal hearts and those with congenital heart disease with moderate success. Following cardioversion, neonates with normal hearts may be followed or may be treated with digoxin or propranolol for 6-12 mo, after which the medication can usually be discontinued, as neonatal atrial flutter generally does not recur.

Atrial fibrillation is uncommon in children and is rare in infants. The atrial excitation is chaotic and more rapid (400-700 beats/min) and produces an irregularly irregular ventricular response and pulse (Fig. 435-9). This rhythm disorder is often associated with atrial enlargement or disease. Atrial fibrillation may be seen in older children with rheumatic mitral valve stenosis. It is also seen rarely as a complication of atrial surgery, in patients with left atrial enlargement secondary to left AV valve insufficiency, and in patients with WPW syndrome. Thyrotoxicosis, pulmonary embolism, pericarditis, or cardiomyopathy may be suspected in a previously normal older child or adolescent with atrial fibrillation. Very rarely, atrial fibrillation may be familial. The best initial treatment is **rate control,** most effectively with calcium channel blockers, to limit the ventricular rate during atrial fibrillation. Digoxin is not given if WPW syndrome is present. Normal sinus rhythm may be restored with intravenous procainamide, ibutilide or amiodarone, or by DC cardioversion, and DC cardioversion is the first choice in hemodynamically unstable patients. Patients with chronic atrial fibrillation are at risk for the development of thromboembolism and stroke and should undergo anticoagulation with warfarin. Patients being treated by elective cardioversion should also undergo anticoagulation.

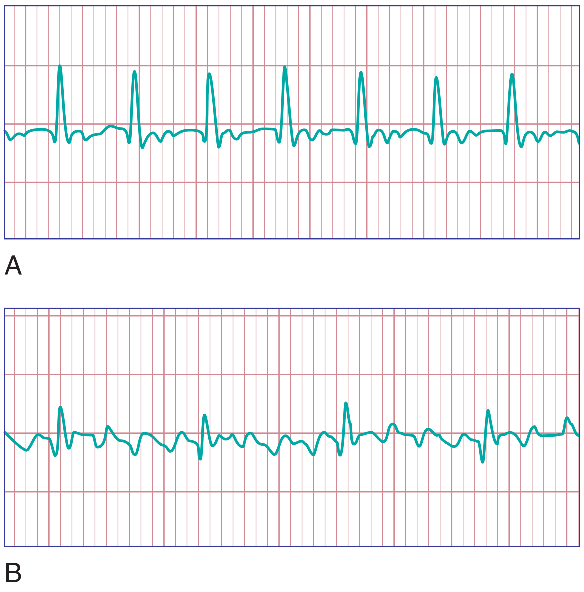

Figure 435-8 Neonatal atrial flutter. Note that the flutter waves are not obvious in the first tracing **(A)** but once a dose of adenosine is given, flutter waves at a rate of about 450 beats/min emerge **(B).**

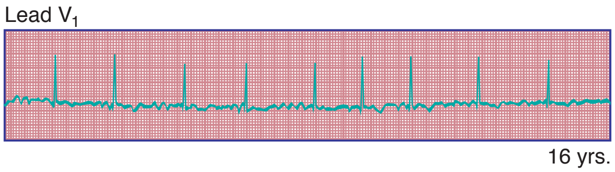

Figure 435-9 **Atrial fibrillation, characterized by the absence of clear P waves and an irregularly irregular ventricular response.** One can appreciate the irregular, rapid undulations (F waves). Fibrillatory waves may not be visible in all leads and should be carefully sought in every tracing with irregular R-R intervals. Note that no 2 R-R intervals are the same.

435.4 Ventricular Tachyarrhythmias

George F. Van Hare

Ventricular tachycardia (VT) is less common than SVT in pediatric patients. VT is defined as at least 3 PVCs at >120 beats/min (Fig. 435-10). It may be paroxysmal or incessant. VT may be associated with myocarditis, anomalous origin of a coronary artery, arrhythmogenic right ventricular dysplasia, mitral valve prolapse, primary cardiac tumors, and dilated or hypertrophic cardiomyopathy. It is seen with prolonged QT interval of either congenital or acquired (proarrhythmic drugs) causation, WPW syndrome, and drug use (cocaine, amphetamines). It may develop years after intraventricular surgery (especially tetralogy of Fallot and related defects) or occur without obvious organic heart disease. VT must be distinguished from SVT with aberrancy or rapid conduction over an accessory pathway (Table 435-2). The presence of clear capture and fusion beats confirms the diagnosis of VT. Although some children tolerate rapid ventricular rates for many hours, this arrhythmia should be promptly treated because hypotension and degeneration into ventricular fibrillation may result. For patients who are hemodynamically stable, intravenous amiodarone, lidocaine, or procainamide are the initial drugs of choice. If treatment is to be successful, it is critical to search for and correct any underlying abnormalities such as electrolyte imbalance, hypoxia, or drug toxicity. Amiodarone is the **treatment of choice** during cardiac arrest (see Chapter 67). Hemodynamically unstable patients with VT should be immediately treated with DC cardioversion. Overdrive ventricular pacing, through temporary pacing wires or a permanent pacemaker, may also be effective, although it may cause the arrhythmia to deteriorate into ventricular fibrillation. In the neonatal period, VT may be associated with an anomalous left coronary artery (see Chapter 432.2) or a myocardial tumor.

Unless a clearly reversible cause is identified, electrophysiologic study is usually indicated for patients in whom VT has developed, and depending on the findings, catheter ablation and/or ICD implantation may be indicated.

A related arrhythmia, **ventricular accelerated rhythm**, is occasionally seen in infants. It is defined the same way as VT, but the rate is only slightly faster than the coexisting sinus rate (within 10%). It is generally benign and resolves spontaneously.

Ventricular fibrillation is a chaotic rhythm that results in death unless an effective ventricular beat is rapidly re-established (see Fig. 435-10). Usually, cardiopulmonary resuscitation and DC defibrillation are necessary. If defibrillation is ineffective or fibrillation recurs, amiodarone or lidocaine may be given intravenously and defibrillation repeated (see Chapter 67). After recovery from ventricular fibrillation, a search should be made for the underlying cause. **Electrophysiologic study** is indicated for patients who have survived

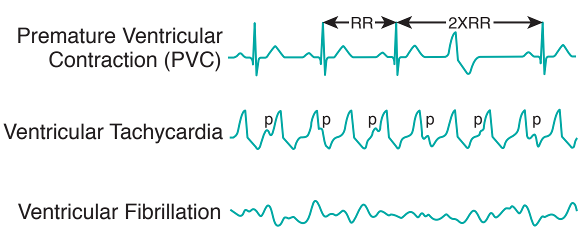

Figure 435-10 **Ventricular arrhythmias.** *(From Park MY:* Pediatric cardiology for practitioners, *ed 5, Philadelphia, 2008, Mosby/Elsevier, p. 429, Fig. 24-6.)*

Table 435-2 Diagnosis of Tachyarrhythmias: Electrocardiographic Findings

	HEART RATE (BEATS/MIN)	P WAVE	QRS DURATION	REGULARITY
Sinus tachycardia	<230	Always present, normal axis	Normal	Rate varies with respiration
Atrial tachycardia	180-320	Present Abnormal P wave morphology and axis	Normal or prolonged (with aberration)	Usually regular but ventricular response may be variable because of Wenckebach conduction
Atrial fibrillation	120-180	Fibrillatory waves	Normal or prolonged (with aberration)	Irregularly irregular (no 2 R-R intervals alike)
Atrial flutter	Atrial: 250-400 Ventricular response variable: 100-320	Sawtoothed flutter waves	Normal or prolonged (with aberration)	Regular ventricular response (e.g., 2:1, 3:1, 3:2, and so on)
Junctional tachycardia	120-280	Atrioventricular dissociation with no fusion, and normal QRS capture beats	Normal or prolonged (with aberration)	Regular (except with capture beats)
Ventricular tachycardia	120-300	Atrioventricular dissociation with capture beats and fusion beats	Prolonged for age	Regular (except with capture beats)

ventricular fibrillation unless a clearly reversible cause is identified. If WPW syndrome is noted, catheter ablation should be performed. For patients in whom no correctable abnormality can be found, an ICD is nearly always indicated, because of the high risk of sudden death.

435.5 Long QT Syndromes

George F. Van Hare

Long QT syndromes (LQTS) are genetic abnormalities of ventricular repolarization, with an estimated incidence of about 1 per 10,000 births (Table 435-3). They present as a long QT interval on the surface electrocardiogram and are associated with malignant ventricular arrhythmias (torsades de pointes and ventricular fibrillation). They are a cause of syncope and sudden death and may be the cause of some cases of sudden infant death syndrome, drowning, and intrauterine fetal demise. In perhaps 80% of cases, there is an identifiable genetic mutation. The old distinction between dominant and recessive forms of the disease (Romano-Ward syndrome vs. Jervell-Lange-Nielsen syndrome) is no longer made, as the latter recessive condition is known to be a result of the homozygous state. Jervell-Lange-Nielsen syndrome is associated with congenital sensorineural deafness. Asymptomatic but at-risk patients carrying the gene mutation may not all have a

Table 435-4 Acquired Causes of QT Prolongation*

DRUGS
Antibiotics—erythromycin, clarithromycin, azithromycin, telithromycin, trimethoprim/sulfamethoxazole, fluoroquinolones†
Antifungal agents†—fluconazole, itraconazole, ketoconazole
Antiprotozoal agents—pentamidine isethionate
Antihistamines—astemizole, terfenadine (Seldane; Seldane has been removed from the market for this reason)
Antidepressants—tricyclics such as imipramine (Tofranil), amitriptyline (Elavil), desipramine (Norpramin), and doxepin (Sinequan)
Antipsychotics—haloperidol, risperidone, phenothiazines such as thioridazine (Mellaril) and chlorpromazine (Thorazine), selective serotonin uptake inhibitors
Antiarrhythmic agents
Class 1A (sodium channel blockers)—quinidine, procainamide, disopyramide
Class III (prolong depolarization)—amiodarone (rare), bretylium, dofetilide, *N*-acetyl-procainamide, sotalol
Lipid-lowering agents—probucol
Antianginals—bepridil
Diuretics (through K^+ loss)—furosemide (Lasix), ethacrynic acid (bumetanide [Bumex])
Opiates—methadone, oxycodone
Oral hypoglycemic agents—glibenclamide, glyburide
Organophosphate insecticides
Motility agents—cisapride, domperidone
Vasodilators—prenylamine
Other drugs—Ondansetron, HIV protease inhibitors, Chinese herbs
ELECTROLYTE DISTURBANCES
Hypokalemia—diuretics, hyperventilation
Hypocalcemia
Hypomagnesemia
UNDERLYING MEDICAL CONDITIONS
Bradycardia—complete atrioventricular block, severe bradycardia, sick sinus syndrome
Myocardial dysfunction—anthracycline cardiotoxicity, congestive heart failure, myocarditis, cardiac tumors
Endocrinopathy—hyperparathyroidism, hypothyroidism, pheochromocytoma
Neurologic—encephalitis, head trauma, stroke, subarachnoid hemorrhage
Nutritional—alcoholism, anorexia nervosa, starvation

*A more exhaustive updated list of medications that can prolong the QTc interval is available at the University of Arizona Center for Education and Research of Therapeutics website (www.azcert.org).
†Combinations of quinolones plus azoles increase the risk of prolonged QT intervals.
From Park MY: Pediatric cardiology for practitioners, *ed 5, Philadelphia, 2008, Mosby/Elsevier, p. 433, Box 24-1.*

prolonged QT duration. QT interval prolongation may become apparent with exercise or during catecholamine infusions.

Genetic studies have identified mutations in cardiac potassium and sodium channels (see Table 435-3). Additional forms (up to 13 variants) of LQTS have been described, but these are much more uncommon. Genotype may predict clinical manifestations; for example, **LQT1 events are usually stress induced,** whereas events in **LQT3 often occur during sleep.** LQT2 events have an intermediate pattern. LQT3 has the highest probability for sudden death, followed by LQT2 and then LQT1. Drugs may prolong the QT interval directly but more often do so when drugs such as erythromycin or ketoconazole inhibit their metabolism (Table 435-4).

The **clinical manifestation** of LQTS in children is most often a syncopal episode brought on by exercise, fright, or a sudden startle; some events occur during sleep (LQT3). Patients can initially be seen with seizures, presyncope, or palpitations; approximately 10% are initially in cardiac arrest. The diagnosis is based on electrocardiographic and clinical criteria. Not all patients with long QT intervals have LQTS, and patients with normal QT intervals on a resting electrocardiogram may have LQTS. A heart rate–corrected QT interval of >0.47 sec is highly indicative, whereas a QT interval of >0.44 sec is suggestive. Other features include notched T waves in 3 leads, T-wave alternans, a low heart rate for age, a history of syncope (especially with stress), and a familial history of either LQTS or unexplained sudden death. Twenty-four hour Holter monitoring and exercise testing are adjuncts to the diagnosis. Genotyping is available and can identify the mutation is approximately 80% of patients known to have LQTS by clinical criteria. Genotyping is not useful in ruling out the diagnosis in individuals suspected of having the disease, but when positive is very useful in identifying asymptomatic affected relatives of the index case.

Short QT syndromes (see Table 435-3) manifest with atrial or ventricular fibrillation and are associated with syncope and sudden death. They are often caused by a gain-of-function mutation in cardiac potassium channels.

Treatment of LQTS includes the use of **β-blocking agents** at doses that blunt the heart rate response to exercise. Propranolol and nadolol may be more effective than atenolol and metoprolol. Some patients require a **pacemaker** because of drug-induced bradycardia. In patients with continued syncope despite treatment, an implantable cardiac defibrillator is indicated for those who do not respond to β-blocking drugs and those who have experienced cardiac arrest. Genotype-phenotype correlative studies have suggested that β-blocking agents are not effective in patients with LQT3, and in those individuals, an ICD is usually indicated.

435.6 Sinus Node Dysfunction

George F. Van Hare

Sinus arrest and **sinoatrial block** may cause a sudden pause in the heartbeat. The former is presumably caused by failure of impulse formation within the sinus node and the latter by a block between the sinus pacemaker complex and the surrounding atrium. These arrhythmias are rare in childhood except in patients who have had extensive atrial surgery.

Sick sinus syndrome is the result of abnormalities in the sinus node or atrial conduction pathways, or both. This syndrome may occur in the absence of congenital heart disease and has been reported in siblings, but it is most commonly seen after surgical correction of congenital heart defects, especially the Fontan procedure and the atrial switch (Mustard or Senning) operation for transposition of the great

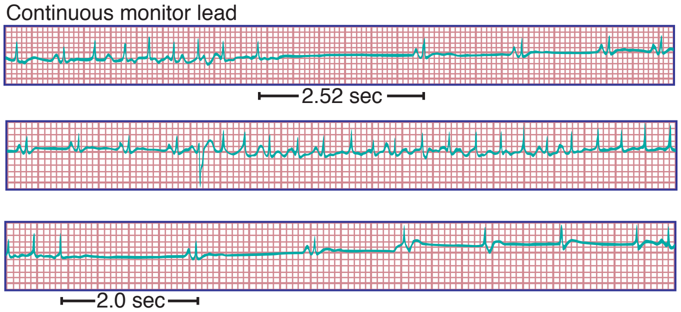

Figure 435-11 The "tachy-brady" syndrome with sinus node dysfunction. Note the bursts of supraventricular tachycardia, probably multifocal atrial in origin, followed by long periods of sinus arrest and by sinus bradycardia. Often, symptoms are caused by the long sinus pauses following termination of tachycardia, rather than by the tachycardia itself.

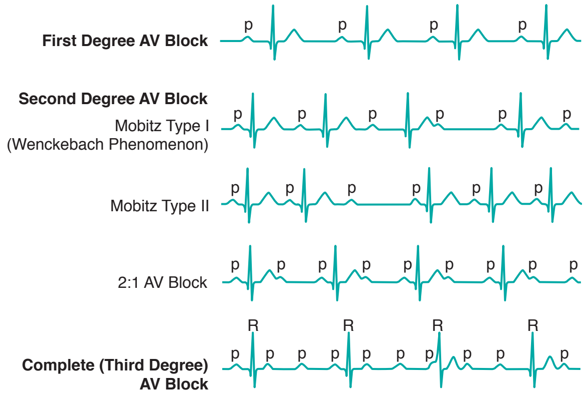

Figure 435-12 Atrioventricular block. *(From Park MY:* Pediatric cardiology for practitioners, *ed 5, Philadelphia, 2008, Mosby/Elsevier, p. 446, Fig. 25-1.)*

arteries. Clinical manifestations depend on the heart rate. Most patients remain asymptomatic without treatment, but dizziness and syncope can occur during periods of marked sinus slowing with failure of junctional escape (Fig. 435-11). Pacemaker therapy is indicated in patients who experience symptoms such as exercise intolerance or syncope.

Patients with sinus node dysfunction may also have episodes of SVT **("tachy-brady syndrome")** with symptoms of palpitations, exercise intolerance, or dizziness. Treatment must be individualized. Drug therapy to control tachyarrhythmias (propranolol, sotalol, amiodarone) may suppress sinus and AV node function to such a degree that further symptomatic bradycardia may be produced. Therefore, insertion of a pacemaker in conjunction with drug therapy is usually necessary for such patients, even in the absence of symptoms ascribable to low heart rate.

435.7 AV Block

George F. Van Hare

AV block may be divided into 3 forms. In **1st-degree AV block,** the PR interval is prolonged, but all the atrial impulses are conducted to the ventricle (Fig. 435-12). In **2nd-degree AV block,** not every atrial impulse is conducted to the ventricle. In the variant of 2nd-degree block known as the **Wenckebach type** (also called **Mobitz type I**), the PR interval increases progressively until a P wave is not conducted. In the cycle following the dropped beat, the PR interval normalizes (see Fig. 435-12). In **Mobitz type II,** there is no progressive conduction delay or subsequent shortening of the PR interval after a blocked beat. This conduction defect is less common but has more potential to cause syncope and may be progressive. A related condition is **high-grade 2nd-degree AV block**, in which 2 or more P waves in a row fail to conduct. This is even more dangerous. In **3rd-degree AV block (complete heart block),** no impulses from the atria reach the ventricles (see Fig. 435-12). An independent escape rhythm is usually present, but may not be reliable, leading to symptoms such as syncope.

Congenital complete AV block in children is presumed to be caused by autoimmune injury of the fetal conduction system by maternally derived immunoglobulin G antibodies (anti-SSA/Ro, anti-SSB/La) in a mother with overt or, more often, asymptomatic systemic lupus erythematosus or Sjögren syndrome. Autoimmune disease accounts for 60-70% of all cases of congenital complete heart block and ≈80% of cases in which the heart is structurally normal (Fig. 435-13). A mutation of the homeobox gene Nkx2-5 is described in which congenital AV block is seen most commonly in association with atrial septal defects. Complete AV block is also seen in patients with complex congenital heart disease and abnormal embryonic development of the

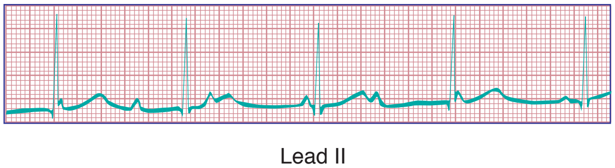

Figure 435-13 Congenital complete atrioventricular (AV) block. The ventricular rate is regular at 53 beats/min. The atrial rate is somewhat variable, from 65-95 beats/min, and completely dissociated from the ventricle. The QRS morphology is normal, which is common in congenital complete AV block.

conduction system. It has been associated with myocardial tumors and myocarditis. It is a known complication of myocardial abscess secondary to endocarditis. It is also seen in genetic abnormalities including LQTS and Kearn-Sayre syndrome. It is also a complication of congenital heart disease repair and, in particular, repairs involving ventricular septal defect closure.

The incidence of congenital complete heart block is 1 per 20,000-25,000 live births; a high fetal loss rate may cause an underestimation of its true incidence. In some infants of mothers with systemic lupus erythematosus, complete heart block is not present at birth but develops within the 1st 3-6 mo after birth. The arrhythmia is often diagnosed in the fetus (secondary to the dissociation between atrial and ventricular contractions seen on fetal echocardiography) and may produce hydrops fetalis. Maternal treatment with steroids to halt progression or reverse AV block is controversial. Infants with associated congenital heart disease and heart failure have a high mortality rate.

In older children with otherwise normal hearts, the condition is often asymptomatic, although syncope and sudden death may occur. Infants and toddlers may have night terrors, tiredness with frequent naps, and irritability. The peripheral pulse is prominent as a result of the compensatory large ventricular stroke volume and peripheral vasodilation; systolic blood pressure is elevated. Jugular venous pulsations occur irregularly and may be large when the atrium contracts against a closed tricuspid valve (cannon wave). Exercise and atropine may produce an acceleration of ≥10-20 beats/min. Systolic murmurs are frequently audible along the left sternal border, and apical mid-diastolic murmurs are not unusual. The 1st heart sound is variable, as a result of variable ventricular filing with AV dissociation. AV block results in enlargement of the heart on the basis of increased diastolic ventricular filling.

The **diagnosis** is confirmed by electrocardiography; the P waves and QRS complexes have no constant relationship (see Fig. 435-13). The

QRS duration may be prolonged, or it may be normal if the heartbeat is initiated high in the AV node or bundle of His.

The **prognosis** for congenital complete heart block is usually favorable; patients who have been observed to the age of 30-40 yr have lived normal, active lives. Some patients have episodes of exercise intolerance, dizziness, and syncope (Stokes-Adams attacks); this symptom requires the implantation of a permanent cardiac pacemaker. Pacemaker implantation should be considered for patients who develop symptoms such as progressive cardiac enlargement, prolonged pauses, or daytime average heart rates of ≤50 beats/min. In addition, prophylactic pacemaker implantation in adolescents is reasonable considering the low risk of the implant procedure and the difficulty in predicting who will develop sudden severe symptoms.

Cardiac pacing is recommended in neonates with low ventricular rates (≤50 beats/min), evidence of heart failure, wide complex rhythms, or congenital heart disease. Isoproterenol, atropine, or epinephrine may be used to try to increase the heart rate temporarily until pacemaker placement can be arranged. Transthoracic epicardial pacemaker implants have traditionally been used in infants; transvenous placement of pacemaker leads is available for young children. Postsurgical complete AV block can occur after any open heart procedure requiring suturing near the AV valves or crest of the ventricular septum. Postoperative heart block is initially managed with temporary pacing wires. The likelihood of a return to sinus rhythm after 10-14 days is low; a permanent pacemaker is recommended after that time.

Chapter 436
Sudden Death

George F. Van Hare

Sudden death other than sudden infant death syndrome (see Chapter 375) is rare in children younger than 18 yr. Sudden death can be divided into either traumatic or nontraumatic origin. Traumatic causes of sudden death are the most common in children; these include motor vehicle crashes, violent deaths, recreational deaths, and occupational deaths. Nontraumatic sudden deaths are often the result of specific cardiac causes. The incidence of sudden death varies from 0.8-6.2 per 100,000 per year in children and adolescents as opposed to the higher incidence of sudden cardiac death in adults of 1 per 1,000. Approximately 65% of sudden deaths are a result of heart-related problems in patients with either normal or congenitally (corrected, palliated, or unoperated) abnormal hearts. Competitive high-school sports (basketball, football) are high-risk environmental factors. The most common cause of death in competitive athletes is hypertrophic cardiomyopathy, with or without obstruction to left ventricular outflow. Table 436-1 lists other potential causes. These can be classified as structural abnormalities, including aortic stenosis and coronary artery abnormalities; myocardial disease, such as myocarditis; conduction system disease, including long QT syndrome; and miscellaneous causes, including pulmonary hypertension and commotio cordis. Symptoms may be absent before the event but, if present, include syncope, chest pain, dyspnea, and palpitations. Patients may have a family history of heart disease (dilated or hypertrophic cardiomyopathy, long QT interval, arrhythmogenic right ventricular dysplasia, Brugada or Marfan syndromes) or sudden death. Death often follows exertion or exercise.

MECHANISM OF SUDDEN DEATH

There are 3 mechanisms of sudden death: arrhythmic, nonarrhythmic cardiac (circulatory and vascular causes), and noncardiac. Ventricular fibrillation, while the most common final cause of sudden death in adults, is only the final cause in 10-20% of children with sudden cardiac death. More commonly, bradycardia leads either to ventricular fibrillation or asystole (see Chapter 435).

CONGENITAL HEART DISEASE

Valvar aortic stenosis is the congenital defect most commonly associated with sudden death in children. Historically, approximately 5% of children with this disease die, although this has become quite rare in the modern era. A history of syncope, chest pain, and evidence of severe obstruction and left ventricular hypertrophy are risk factors (see Chapter 434.5).

Coronary artery anomalies are also commonly associated with sudden death in children and adolescents. The most common abnormality associated with sudden death is the origin of the left main coronary artery from the right sinus of Valsalva. The coronary artery therefore courses between the aorta and pulmonary artery, and may also be intramural in course. Exercise results in a rise in pulmonary and aortic pressure, and this is thought to compress the left main coronary artery and results in ischemia due to compression or kinking. Anomalous origin of the right coronary artery from the left sinus of Valsalva is much more common, but only rarely is a cause of sudden death.

CARDIOMYOPATHY

All 3 major types of cardiomyopathy (hypertrophic, dilated, and restrictive) are associated with sudden death in the pediatric population; sudden death may be the initial manifestation of the cardiomyopathy (see Chapter 439).

Hypertrophic cardiomyopathy (HCM) is the most common cause of sudden death in the athletic adolescent. The annual risk of sudden death in young patients with HCM is 2% per year. Risk factors for sudden death include a family history of sudden death, symptoms, ventricular arrhythmias, and presentation at an early age. Many patients with HCM have obstruction to the left ventricular outflow tract. The mechanism of sudden death is arrhythmic and may be secondary to development of dynamic obstruction with exercise and resultant loss of cardiac output, or may be related to cardiac ischemia. Thus, patients without left ventricular outflow tract obstruction are also at risk of sudden death. The **dilated cardiomyopathies** are also associated with sudden cardiac death in children, although the risk is clearly lower than in adults.

Arrhythmogenic right ventricular dysplasia is a specific form of cardiomyopathy associated with exercise-induced ventricular arrhythmias and sudden death. The diagnosis can be difficult; MRI, electrophysiology study, or endomyocardial biopsy is used with limited reliability. Pathology includes transmural fatty replacement of right ventricular myocardium, with patchy areas of fibrosis.

Myocarditis has been found commonly on pathology of patients with sudden death of unknown etiology. Symptoms prior to sudden death may be absent, or may include overt heart failure or subtle findings such as a high heart rate. Pediatric patients may have complete heart block or ventricular arrhythmias with this disease.

CARDIAC ARRHYTHMIA

A primary conduction system abnormality may result in sudden death. Causes include Wolff-Parkinson-White (WPW) syndrome, long QT syndrome, and Brugada syndrome. Besides causing supraventricular tachycardia, WPW syndrome can result in atrial fibrillation with rapid conduction across the accessory pathway leading to ventricular fibrillation and sudden death (Fig. 436-1). This is unusual in pediatric patients but has an increasing incidence in adolescence. In adults, there is an incidence of sudden death in asymptomatic patients of 1 per 1,000 patient-years, but this rate may well be higher in children, who by definition have not survived to adulthood. As digoxin and verapamil can augment conduction down accessory pathways, these drugs are contraindicated in WPW syndrome.

Long QT syndrome (see Chapter 435), a group of channelopathies that affect ventricular repolarization, is also associated with sudden

*Common.

death (Fig. 436-2). The mechanism of sudden death is polymorphic ventricular tachycardia (torsades de pointes) (Fig. 436-3). An initial presentation of sudden cardiac death is found in 9% of patients. Thus, treatment of asymptomatic patients with a long QT interval on electrocardiogram (ECG) and positive family history is advised.

Acquired long QT intervals may be seen in patients with marked electrolyte abnormalities, central nervous system injury, or starvation (including bulimia and anorexia nervosa). Medications can also result in prolongation of the QT interval (see Table 435-4 in Chapter 435). These patients are also at risk of malignant ventricular arrhythmias, and correction of the underlying problem may be necessary to reduce the risk of sudden death.

Brugada syndrome, an autosomal dominant disorder, caused in approximately 30% of patients to a mutation in the *SCN5A* gene, is associated with sudden cardiac death, often associated with fever, drugs, nighttime electrolyte disorders, or after a large meal (see Fig. 436-4). Typical ECG findings include coved ST segment elevations in leads V_1-V_3; death results from either ventricular fibrillation or tachycardia.

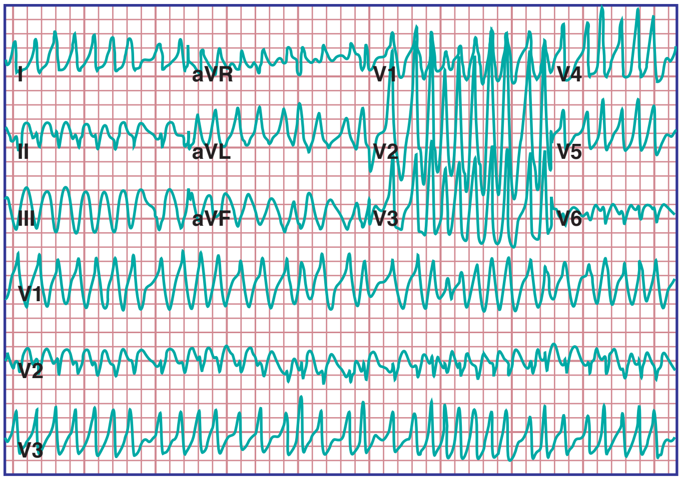

Figure 436-1 **Atrial fibrillation in a patient with Wolff-Parkinson-White syndrome and rapid conduction to the ventricle.** Note the wide QRS complexes, a result of full preexcitation, and the irregularly irregular ventricular response, caused by the atrial fibrillation.

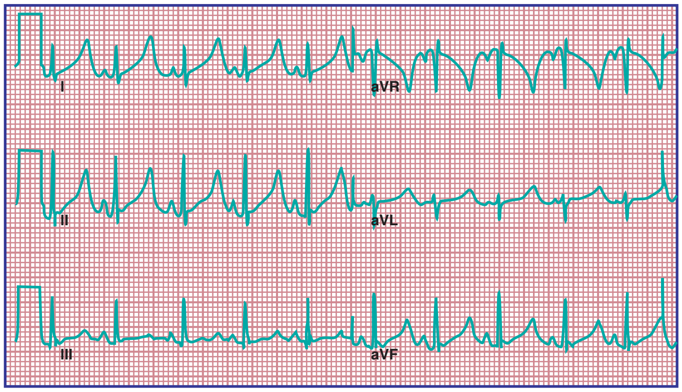

Figure 436-2 **Long QT syndrome in a neonate.** QTc is markedly prolonged. T waves are also peaked and abnormal in appearance.

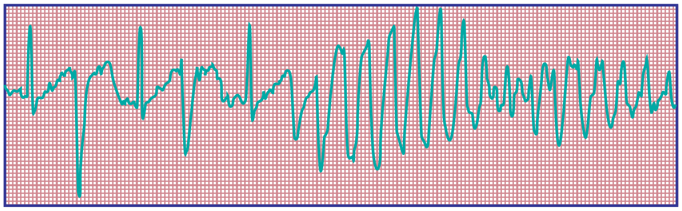

Figure 436-3 **Episode of torsades de pointes in a patient with long QT syndrome.**

MISCELLANEOUS CAUSES

Commotio cordis is a nearly universally fatal condition that follows blunt nonpenetrating trauma to the chest (e.g., from a baseball or hockey puck). Occasionally, innocent-appearing chest blows incurred at home or at a playground may be fatal. Patients experience immediate ventricular fibrillation in the absence of identifiable cardiac trauma (contusion, hematoma, lacerated coronary artery). Historically death results from ventricular fibrillation that is unresponsive to resuscitative efforts in 85-90% of children. Immediate direct current defibrillation may be

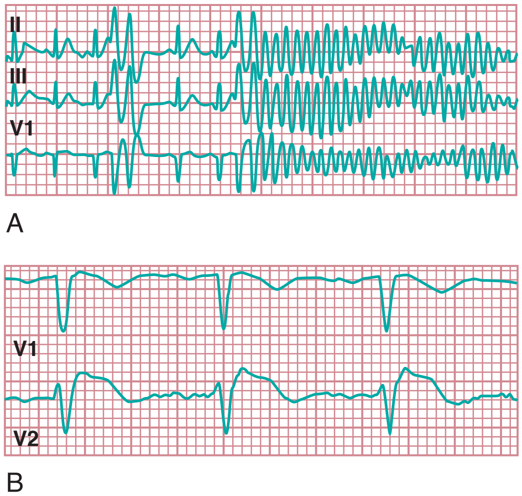

Figure 436-4 Brugada syndrome. **A,** Frequent ventricular ectopy and sustained polymorphic ventricular tachycardia. **B,** Persistent coved type ST segment elevation in lead V_1 and V_2 characteristic for Brugada type I. *From Talib S, van de Poll SE: Brugada syndrome diagnosed after Ramadan.* Lancet *382:100, 2013.*

effective, if available, particularly if employed immediately; however, it is reported to be successful in only approximately 25% of cases.

EVALUATION AND THERAPY FOR RESUSCITATED PATIENTS

It is important to focus therapy on potentially reversible causes of sudden death. These include correction of major hemodynamic defects, pacing therapy for a patient with bradycardia, or supportive therapy for myocarditis. Unfortunately, reversible causes are not always found in young cardiac arrest survivors. Added to this dilemma is the fact that there is a limited ability to predict antiarrhythmic drug response or risk of recurrence. Thus, the implantable cardioverter defibrillator is the **therapy of choice** for survivors of arrhythmic sudden death.

MEDICATION FOR ATTENTION-DEFICIT DISORDER

There has been some concern about the possibility that stimulant medications prescribed for the treatment of children with attention-deficit disorder could potentially increase the risk of sudden death. The concern arises from a limited number of reports to the U.S. Food and Drug Administration of sudden death of unknown etiology in individuals taking stimulant medications, most of whom are adults. In a few cases, left ventricular hypertrophy caused by hypertension, coarctation of the aorta, or HCM has been identified at postmortem examination. There are no prospective studies to support the notion that these medications increase the risk, and little or no evidence that electrocardiographic screening will reliably identify a subgroup at risk. Some suggest ECG screening of children prior to starting these medications, but there is no consensus that such an approach is effective.

PREVENTION OF SUDDEN DEATH

The probability of survival to hospital discharge for a young patient who experiences an out-of-hospital cardiac arrest is <20%. The presence of immediate automatic external defibrillators, when combined with standard cardiopulmonary resuscitation at the site of exercise (gym, track, basketball, or football arena), may improve survival substantially. Thus, identifying patients at risk is extremely important.

Many of the more common causes of sudden death in children and adolescents can be identified from the patient's history (prodromal symptoms), the family history, and physical examination. The American Academy of Pediatrics makes available a downloadable "Preparticipation Physical Evaluation" form that is useful for this purpose (http://www.aap.org). Of paramount importance is the careful evaluation of any child who experiences syncope in association with exercise, as this may be the last opportunity to diagnose a life-threatening condition in such a patient.

Patient avoidance of high-risk behavior (cocaine use, anorexia nervosa) and knowledge of drug side effects or drug interactions and contraindications is critical. Chest-protecting equipment has not been shown to prevent commotio cordis. Prompt bystander cardiopulmonary resuscitation and rapid defibrillation by an automatic external defibrillator has the best chance of leading to survival. Family survivors of victims of sudden death should be evaluated for genetic causes such as long QT syndrome and HCM.

The use of a preparticipation ECG for the detection of those athletes at risk for sudden death is controversial. Because many athletes either have no pre-event symptoms or are unwilling to admit to symptoms for fear of not being able to play, some have proposed that the ECG may identify a small but at-risk group with HCM or the prolonged QT, Brugada, or WPW syndromes. Preparticipation ECG testing is mandatory in several European countries but not in the United States. If the ECG is positive, echocardiography is performed. Cost-effectiveness studies suggest that the cost for implementation of a national program in the United States would be prohibitive because of the low incidence of sudden death in the pediatric population, the high rate of false-positive ECGs, and the difficulty in definitively excluding cardiac disease in patients with borderline ECG findings. Although studies of regional or national screening programs have suggested some benefit (e.g., the Veneto region of Italy) others have failed to demonstrate any effect of screening on the background incidence of sudden death in young individuals.

Section 5

Acquired Heart Disease

Chapter 437

Infective Endocarditis

Daniel Bernstein

Infective endocarditis includes acute and subacute bacterial endocarditis, as well as nonbacterial endocarditis caused by viruses, fungi, and other microbiologic agents. It is a significant cause of morbidity and mortality in children and adolescents despite advances in the management and prophylaxis of the disease with antimicrobial agents. The inability to eradicate infective endocarditis by prevention or early treatment stems from several factors. The disease represents a complex interplay between a pathogen and host factors such as endothelial disruption and immune function that is still not completely understood; the nature of the infecting organism has changed over time; diagnosis may be difficult during early stages and is thus often delayed until a more serious infection has set in; and special risk groups have emerged, including intravenous drug users; survivors of cardiac surgery, especially those with mechanical prosthesis; patients taking immunosuppressant medications; and patients who require chronic intravascular catheters. Some patients get endocarditis on what was thought to be a previously healthy native valve, although on surgical inspection is found to have mild structural abnormalities.

ETIOLOGY

Viridans-type streptococci (α-hemolytic streptococci) and *Staphylococcus aureus* remain the leading causative agents for endocarditis in pediatric patients. Other organisms cause endocarditis less frequently and, in ≈6% of cases, blood cultures are negative for any organisms (Table 437-1). No relationship exists between the infecting organism and the type of congenital defect, the duration of illness, or the age of the child. Staphylococcal endocarditis is more common in patients with no underlying heart disease; viridans group streptococcal infection is more common after dental procedures; group D enterococci are seen more often after lower bowel or genitourinary manipulation; *Pseudomonas aeruginosa* or *Serratia marcescens* is seen more frequently in intravenous drug users; and fungal organisms are encountered after open heart surgery. Coagulase-negative staphylococci are common in the presence of an indwelling central venous catheter.

EPIDEMIOLOGY

Infective endocarditis is often a complication of congenital or rheumatic heart disease but can also occur in children without any abnormal valves or cardiac malformations. In developed countries, congenital heart disease is the overwhelming predisposing factor. Endocarditis is rare in infancy; in this age group, it usually follows open heart surgery or is associated with a central venous line.

Patients with congenital heart lesions where there is turbulent blood flow because of a hole or stenotic orifice, especially if there is a high-pressure gradient across the defect, are most susceptible to endocarditis. This turbulent flow traumatizes the vascular endothelium, creating a substrate for deposition of fibrin and platelets, leading to the formation of a nonbacterial thrombotic embolus (NBTE) that is thought to be the initiating lesion for infective endocarditis. Biofilms form on the surface of implanted mechanical devices such as valves, catheters, or pacemaker wires that also serve as the adhesive substrate for infection. The development of transient bacteremia then colonizes this NBTE or biofilm, leading to proliferation of bacteria within the lesion. Bacterial surface proteins, such as the FimA antigen in viridans streptococci, act as adhesion factors to the NBTE or biofilm, after which bacteria can rapidly proliferate within the vegetation. Given the heavy colonization of mucosal surfaces (the oropharynx, or gastrointestinal, vaginal, or urinary tracts) by potentially pathogenic bacteria, these surfaces are thought to be the origin of this transient bacteremia. There is controversy over the extent to which daily activities (such as brushing or flossing the teeth) versus invasive procedures (such as dental cleanings or surgery) contribute to this bacteremia. Transient bacteremia is reported to occur in 20-68% of patients after tooth brushing and flossing, and even in 7-51% of patients after chewing food. The magnitude of this bacteremia is also similar to that resulting from dental procedures. Maintenance of good oral hygiene may be a more important factor in decreasing the frequency and magnitude of bacteremia.

Children at **highest risk** of adverse outcome after infective endocarditis include those with prosthetic cardiac valves or other prosthetic material used for cardiac valve repair, unrepaired cyanotic congenital heart disease (including those palliated with shunts and conduits), completely repaired defects with prosthetic material or device during the 1st 6 mo after repair, repaired congenital heart disease with residual defects at or adjacent to the site of a prosthetic patch or device, valve stenosis or insufficiency occurring after heart transplantation, permanent valve disease from rheumatic fever (mitral stenosis, aortic regurgitation), and previous infective endocarditis. Patients with high velocity blood flow lesions such as ventricular septal defects and aortic stenosis are also at high risk. In older patients, congenital bicuspid aortic valves and mitral valve prolapse with regurgitation pose additional risks for endocarditis. Surgical correction of congenital heart disease may reduce but does not eliminate the risk of endocarditis, with the exception of repair of a simple atrial septal defect or patent ductus arteriosus without prosthetic material.

In ≈30% of patients with infective endocarditis, a predisposing factor is presumably recognized. Although a preceding dental procedure may be identified in 10-20% of patients, the time of the procedure may range from 1 to 6 mo prior to the onset of symptoms, hence the continued controversy over the absolute risk of infective endocarditis after dental procedures. Primary bacteremia with *S. aureus* is thought to be another risk for endocarditis. The occurrence of endocarditis directly after most routine heart surgery is relatively low, but it can be an antecedent event, especially if prosthetic material is utilized.

Table 437-1	Bacterial Agents in Pediatric Infective Endocarditis
COMMON: NATIVE VALVE OR OTHER CARDIAC LESIONS	
Viridans group streptococci *(Streptococcus mutans, Streptococcus sanguinis, Streptococcus mitis)*	
Staphylococcus aureus	
Group D streptococcus (enterococcus) *(Streptococcus bovis, Streptococcus faecalis)*	
UNCOMMON: NATIVE VALVE OR OTHER CARDIAC LESIONS	
Streptococcus pneumoniae	
Haemophilus influenzae	
Coagulase-negative staphylococci	
Abiotrophia defectiva (nutritionally variant streptococcus)	
Coxiella burnetii (Q fever)*	
Neisseria gonorrhoeae	
*Brucella**	
*Chlamydia psittaci**	
*Chlamydia trachomatis**	
*Chlamydia pneumoniae**	
*Legionella**	
*Bartonella**	
*Tropheryma whipplei** (Whipple disease)	
HACEK group†	
*Streptobacillus moniliformis**	
*Pasteurella multocida**	
Campylobacter fetus	
Culture negative (6% of cases)	
PROSTHETIC VALVE	
Staphylococcus epidermidis	
Staphylococcus aureus	
Viridans group streptococcus	
Pseudomonas aeruginosa	
Serratia marcescens	
Diphtheroids	
Legionella species*	
HACEK group†	
Fungi‡	

*These fastidious bacteria plus some fungi may produce culture-negative endocarditis. Detection may require special media, incubation for more than 7 days, polymerase chain reaction on blood or valve for 16SrRNA (bacteria) or 18SrRNA (fungi), or serologic tests.

†The HACEK group includes *Haemophilus* species *(H. paraphrophilus, H. parainfluenzae, H. aphrophilus), Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* species.

‡*Candida* species, *Aspergillus* species, *Pseudallescheria boydii, Histoplasma capsulatum.*

CLINICAL MANIFESTATIONS

Table 437-2 outlines the manifestations of infective endocarditis.

Early manifestations are usually mild, especially when viridans group streptococci are the infecting organisms. Prolonged fever without other manifestations (except, occasionally, weight loss) that persists for as long as several months may be the only symptom. Alternatively, the onset may be acute and severe, with high, intermittent fever and prostration. Usually, the onset and course vary between these 2 extremes. The symptoms are often nonspecific and consist of low-grade fever with afternoon elevations, fatigue, myalgia, arthralgia, headache, and, at times, chills, nausea, and vomiting. **New or changing heart murmurs** are common, particularly with associated heart failure. Splenomegaly and petechiae are relatively common.

Table 437-2	Manifestations of Infective Endocarditis
HISTORY	
Prior congenital or rheumatic heart disease	
Preceding dental, urinary tract, or intestinal procedure	
Intravenous drug use	
Central venous catheter	
Prosthetic heart valve	
SYMPTOMS

Weight loss	
CNS manifestations (stroke, seizures, headache)	
SIGNS	
Elevated temperature	
Tachycardia	
Embolic phenomena (Roth spots, petechiae, splinter nail bed hemorrhages, Osler nodes, CNS or ocular lesions)	
Janeway lesions	
New or changing murmur	
Splenomegaly	
Arthritis	
Heart failure	
Arrhythmias	
Metastatic infection (arthritis, meningitis, mycotic arterial aneurysm, pericarditis, abscesses, septic pulmonary emboli)	
Clubbing	
LABORATORY	
Positive blood culture	
Elevated erythrocyte sedimentation rate; may be low with heart or renal failure	
Elevated C-reactive protein	
Anemia	
Leukocytosis	
Immune complexes	
Hypergammaglobulinemia	
Hypocomplementemia	
Cryoglobulinemia	
Rheumatoid factor	
Hematuria	
Renal failure: azotemia, high creatinine (glomerulonephritis)	
Chest radiograph: bilateral infiltrates, nodules, pleural effusions	
Echocardiographic evidence of valve vegetations, prosthetic valve dysfunction or leak, myocardial abscess, new-onset valve insufficiency	

CNS, central nervous system.

Serious neurologic complications such as embolic strokes, cerebral abscesses, mycotic aneurysms, and hemorrhage are most often associated with staphylococcal disease and may be late manifestations. Meningismus, increased intracranial pressure, altered sensorium, and focal neurologic signs are manifestations of these complications. Myocardial abscesses may occur with staphylococcal disease and may damage the cardiac conducting system, causing heart block, or may rupture into the pericardium and produce purulent pericarditis. Pulmonary and other systemic emboli are infrequent, except with fungal disease. Many of the classic skin findings develop late in the course of the disease; they are seldom seen in appropriately treated patients. Such manifestations include **Osler nodes** (tender, pea-size intradermal nodules in the pads of the fingers and toes), **Janeway lesions** (painless small erythematous or hemorrhagic lesions on the palms and soles), and **splinter hemorrhages** (linear lesions beneath the nails). These lesions may represent vasculitis produced by circulating antigen–antibody complexes.

Table 437-3 Diagnostic Approach to Uncommon Pathogens Causing Endocarditis

PATHOGEN	DIAGNOSTIC PROCEDURE
Brucella spp.	Blood cultures; serology; culture, immunohistology, and PCR of surgical material
Coxiella burnetii	Serology (IgG phase I >1 in 800); tissue culture, immunohistology, and PCR of surgical material
Bartonella spp.	Blood cultures; serology; culture, immunohistology, and PCR of surgical material
Chlamydia spp.	Serology; culture, immunohistology, and PCR of surgical material
Mycoplasma spp.	Serology; culture, immunohistology, and PCR of surgical material
Legionella spp.	Blood cultures; serology; culture, immunohistology, and PCR of surgical material
Tropheryma whipplei	Histology and PCR of surgical material

IgG, immunoglobulin G; PCR, polymerase chain reaction.
From Moreillon P, Que YA: Infective endocarditis, Lancet *363:139–148, 2004.*

Identification of infective endocarditis is most often based on a high index of suspicion during evaluation of an infection in a child with an underlying risk factor.

DIAGNOSIS

The critical information for appropriate treatment of infective endocarditis is obtained from blood cultures. All other laboratory data are secondary in importance (see Table 437-2). Blood specimens for culture should be obtained as promptly as possible, even if the child feels well and has no other physical findings. Three to 5 separate blood collections should be obtained after careful preparation of the phlebotomy site. Contamination presents a special problem inasmuch as bacteria found on the skin may themselves cause infective endocarditis. The timing of collections is not important because bacteremia can be expected to be relatively constant. In 90% of cases of endocarditis, the causative agent is recovered from the first 2 blood cultures. Bacteremia is low grade in 80% (<100 colony-forming units [CFU]/mL or blood). The laboratory should be notified that endocarditis is suspected so that, if necessary, the blood can be cultured on enriched media for longer than usual (>7 days) to detect nutritionally deficient and fastidious bacteria or fungi. Although bacteremia may occur in the absence of endocarditis, bacteremia secondary to *Streptococcus mutans*, *Streptococcus bovis I*, *Streptococcus mitior*, *Streptococcus sanguis,* and *S. aureus* (in the absence of focal musculoskeletal infection) is highly concerning for endocarditis. Antimicrobial pretreatment of the patient reduces the yield of blood cultures to 50-60%. The microbiology laboratory should be notified if the patient has received antibiotics so that more sophisticated methods can be used to recover the offending agent. Other specimens that may be cultured include scrapings from cutaneous lesions, urine, synovial fluid, abscesses, and, in the presence of manifestations of meningitis, cerebrospinal fluid. Serologic diagnosis or polymerase chain reaction of resected valve tissues is necessary in patients with unusual or fastidious microorganisms (Table 437-3; Fig. 437-1).

The index of suspicion should be high when evaluating infection in a child with an underlying contributing factor. The combination of transthoracic and transesophageal echocardiography enhances the ability to diagnose endocarditis. Two-dimensional echocardiography can identify the size, shape, location, and mobility of the lesion; when combined with Doppler studies, the presence of valve dysfunction

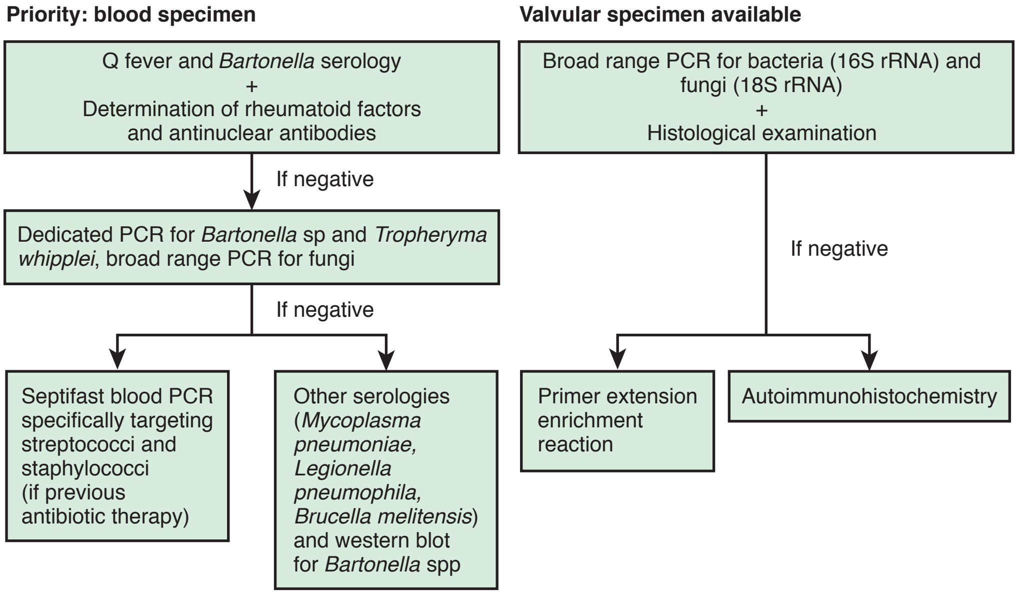

Figure 437-1 Diagnostic tests applied to clinical specimens for the identification of the causative agents of blood culture–negative endocarditis. Septifast, LightCycler SeptiFast (Roche). Serum should be considered a priority specimen, with Q fever and *Bartonella* serologic analysis being routinely done. We also suggest that detection of antinuclear antibodies and rheumatoid factor should be routinely done for diagnosis of noninfective endocarditis. *(From Thuny F, Grisoli D, Collart F, et al. Management of infective endocarditis: challenges and perspectives.* Lancet *379:965–975, 2012, Fig. 2, p. 969.)*

(regurgitation, obstruction) can be determined and its effect on left ventricular performance quantified. Echocardiography may also be helpful in predicting embolic complications, given that lesions >1 cm and fungating masses are at greatest risk for embolization. The absence of vegetations does not exclude endocarditis, and vegetations are often not visualized in the early phases of the disease or in patients with complex congenital heart lesions.

The **Duke criteria** help in the diagnosis of endocarditis. **Major criteria** include (1) positive blood cultures (2 separate cultures for a usual pathogen, 2 or more for less-typical pathogens), and (2) evidence of endocarditis on echocardiography (intracardiac mass on a valve or other site, regurgitant flow near a prosthesis, abscess, partial dehiscence of prosthetic valves, or new valve regurgitant flow). **Minor criteria** include predisposing conditions, fever, embolic-vascular signs, immune complex phenomena (glomerulonephritis, arthritis, rheumatoid factor, Osler nodes, Roth spots), a single, positive blood culture or serologic evidence of infection, and echocardiographic signs not meeting the major criteria. Two major criteria, 1 major and 3 minor, or 5 minor criteria suggest definite endocarditis. A modification of the Duke criteria may increase sensitivity while maintaining specificity. The following minor criteria are added to those already listed: the presence of newly diagnosed clubbing, splenomegaly, splinter hemorrhages, and petechiae; a high erythrocyte sedimentation rate; a high C-reactive protein level; and the presence of central nonfeeding lines, peripheral lines, and microscopic hematuria.

PROGNOSIS AND COMPLICATIONS

Despite the use of antibiotic agents, mortality remains high, in the range of 20-25%. Serious morbidity occurs in 50-60% of children with documented infective endocarditis; the most common is heart failure caused by vegetations involving the aortic or mitral valve. Myocardial abscesses and toxic myocarditis may also lead to heart failure without characteristic changes in auscultatory findings and, occasionally, to life-threatening arrhythmias. Systemic emboli, often with central nervous system manifestations, are a major threat. Pulmonary emboli may occur in children with ventricular septal defect or the tetralogy of Fallot, although massive life-threatening pulmonary embolization is rare. Other complications include mycotic aneurysms, rupture of a sinus of Valsalva, obstruction of a valve secondary to large vegetations, acquired ventricular septal defect, and heart block as a result of involvement (abscess) of the conduction system. Additional complications include meningitis, osteomyelitis, arthritis, renal abscess, purulent pericarditis, and immune complex-mediated glomerulonephritis.

TREATMENT

Antibiotic therapy should be instituted immediately once a definitive diagnosis is made. When virulent organisms are responsible, small delays may result in progressive endocardial damage and are associated with a greater likelihood of severe complications. The choice of antibiotics, method of administration, and length of treatment should be coordinated with consultants from both cardiology and infectious diseases (Tables 437-4 and 437-5). Empirical therapy before the identifiable agent is recovered may be initiated with vancomycin plus gentamicin in patients without a prosthetic valve and when there is a high risk of *S. aureus,* enterococcus, or viridans streptococci (the 3 most common organisms). High serum bactericidal levels must be maintained long enough to eradicate organisms that are growing in relatively inaccessible avascular vegetations. Between 5 and 20 times the minimal in vitro inhibiting concentration must be produced at the site of infection to destroy bacteria growing at the core of these lesions. Several weeks are required for a vegetation to organize completely; therapy must be continued through this period so that recrudescence can be avoided. A total of 4-6 wk of treatment is usually recommended. Depending on the clinical and laboratory responses, antibiotic therapy may require modification and, in some instances, more prolonged treatment is required. With highly sensitive viridans group streptococcal infections, shortened regimens that include oral penicillin for some portion have been recommended. In nonstaphylococcal disease, bacteremia usually resolves in 24-48 hr, whereas fever resolves in 5-6 days with appropriate antibiotic therapy. Resolution with staphylococcal disease takes longer.

If the infection occurs on a valve and induces or increases symptoms and signs of heart failure, appropriate therapy should be instituted, including diuretics, afterload reducing agents, and in some cases, digitalis. Surgical intervention for infective endocarditis is indicated for severe aortic, mitral or prosthetic valve involvement with intractable heart failure. Severe heart failure may be associated with acute valve regurgitation, obstruction, or fistula formation. Rarely, a

Table 437-4 Therapy of Native Valve Endocarditis Caused by Highly Penicillin-Susceptible Viridans Group Streptococci and *Streptococcus bovis*

REGIMEN	DOSAGE* AND ROUTE	DURATION, WK	COMMENTS
Aqueous crystalline penicillin G sodium	12-18 million U/24 hr IV either continuously or in 4 or 6 equally divided doses	4	Preferred in patients with impairment of 8th cranial nerve function or renal function
or			
Ceftriaxone sodium	2 g/24 hr IV/IM in 1 dose ***Pediatric dose***[†]: penicillin 200,000 U/kg per 24 hr IV in 4-6 equally divided doses; ceftriaxone 100 mg/kg per 24 hr IV/IM in 1 dose	4	
Aqueous crystalline penicillin G sodium	12-18 million U/24 hr IV either continuously or in 6 equally divided doses	2	2 wk regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of <20 mL/min, impaired 8th cranial nerve function, or *Abiotrophia*, *Granulicatella*, or *Gemella* spp. infection; gentamicin dosage should be adjusted to achieve peak serum concentration of 3-4 μg/mL and trough serum concentration of <1 μg/mL when 3 divided doses are used; nomogram used for single daily dosing
or			
Ceftriaxone sodium	2 g/24 hr IV/IM in 1 dose	2	
plus			
Gentamicin sulfate[‡]	3 mg/kg per 24 hr IV/IM in 1 dose, or 3 equally divided doses ***Pediatric dose:*** penicillin 200,000 U/kg per 24 hr IV in 4-6 equally divided doses; ceftriaxone 100 mg/kg per 24 hr IV/IM in 1 dose; gentamicin 3 mg/kg per 24 hr IV/IM in 1 dose or 3 equally divided doses[§]	2	
Vancomycin hydrochloride[¶]	30 mg/kg per 24 hr IV in 2 equally divided doses not to exceed 2 g/24 hr unless concentrations in serum are inappropriately low ***Pediatric dose:*** 40 mg/kg per 24 hr IV in 2-3 equally divided doses	4	Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to obtain peak (1 hr after infusion completed) serum concentration of 30-45 μg/mL and a trough concentration range of 10-15 μg/mL

Minimum inhibitory concentration ≤0.12 μg/mL.
*Dosages recommended are for patients with normal renal function.
†Pediatric dose should not exceed that of a normal adult.
‡Other potentially nephrotoxic drugs (e.g., nonsteroidal antiinflammatory drugs) should be used with caution in patients receiving gentamicin therapy.
§Data for once-daily dosing of aminoglycosides for children exist, but no data for treatment of infective endocarditis exist.
¶Vancomycin dosages should be infused during course of at least 1 hr to reduce risk of histamine-release "red man" syndrome.
From Baddour LM, Wilson WR, Bayer AS, et al: Infective endocarditis: diagnosis, antimicrobial therapy, and management of complications, Circulation *111:e394–e433, 2005; correction:* Circulation *112:2373, 2005.*

mycotic aneurysm, rupture of an aortic sinus, intraseptal abscess causing complete heart block, or dehiscence of an intracardiac patch requires an emergency operation. Other surgical indications include failure to sterilize the blood despite adequate antibiotic levels in 7-10 days in the absence of extracardiac infection, myocardial abscess, recurrent emboli, and increasing size of vegetations while receiving therapy. Vegetations (aortic, mitral, prosthetic valve) >10-15 mm are at high risk of embolism. Although antibiotic therapy should be administered for as long as possible before surgical intervention, active infection is not a contraindication if the patient is critically ill as a result of severe hemodynamic deterioration from infective endocarditis. Removal of vegetations and, in some instances, valve replacement may be lifesaving, and sustained antibiotic administration will most often prevent reinfection. Replacement of infected prosthetic valves carries a higher risk.

Fungal endocarditis is difficult to manage and has a poorer prognosis. It has been encountered after cardiac surgery, in severely debilitated or immunosuppressed patients, and in patients on prolonged courses of antibiotics. The drugs of choice are amphotericin B (liposomal or standard preparation) and 5-fluorocytosine. Surgery to excise infected tissue is occasionally attempted, though often with limited success. Recombinant tissue plasminogen activation may help lyse intracardiac vegetations and avoid surgery in some high-risk patients.

PREVENTION

Recommendations by the American Heart Association for antimicrobial prophylaxis before dental and other surgical procedures received a major revision in 2007. A substantial reduction in the number of patients who require prophylactic treatment and the procedures requiring coverage was recommended. The primary reasons for these revised recommendations were that (1) infective endocarditis is much more likely to result from exposure to the more frequent random bacteremias associated with daily activities than from a dental or surgical procedure; (2) routine prophylaxis may prevent "an exceedingly

Table 437-5 Therapy for Endocarditis Caused by Staphylococci in the Absence of Prosthetic Materials

REGIMEN	DOSAGE* AND ROUTE	DURATION	COMMENTS
OXACILLIN-SUSCEPTIBLE STRAINS			
Nafcillin or oxacillin†	12 g/24 hr IV in 4-6 equally divided doses	6 wk	For complicated right-sided IE and for left-sided IE; for uncomplicated right-sided IE, 2 wk
with			
Optional addition of gentamicin sulfate‡	3 mg/kg per 24 hr IV/IM in 2 or 3 equally divided doses	3-5 day	
	Pediatric dose§: Nafcillin or oxacillin 200 mg/kg per 24 hr IV in 4-6 equally divided doses; gentamicin 3 mg/kg per 24 hr IV/IM in 3 equally divided doses		Clinical benefit of aminoglycosides has not been established
For penicillin-allergic (nonanaphylactoid-type) patients:			Consider skin testing for oxacillin-susceptible staphylococci and questionable history of immediate-type hypersensitivity to penicillin
Cefazolin	6 g/24 hr IV in 3 equally divided doses	6 wk	Cephalosporins should be avoided in patients with anaphylactoid-type hypersensitivity to β-lactams; vancomycin should be used in these cases§
with			
Optional addition of gentamicin sulfate	3 mg/kg per 24 hr IV/IM in 2 or 3 equally divided doses ***Pediatric dose:*** cefazolin 100 mg/kg per 24 hr IV in 3 equally divided doses; gentamicin 3 mg/kg per 24 hr IV/IM in 3 equally divided doses	3-5 day	Clinical benefit of aminoglycosides has not been established
OXACILLIN-RESISTANT STRAINS			
Vancomycin¶	30 mg/kg per 24 hr IV in 2 equally divided doses ***Pediatric dose:*** 40 mg/kg per 24 hr IV in 2 or 3 equally divided doses	6 wk	Adjust vancomycin dosage to achieve 1 hr serum concentration of 30-45 μg/mL and trough concentration of 10-15 μg/mL

IE, infective endocarditis.

*Dosages recommended are for patients with normal renal function.

†Penicillin G 24 million U/24 hr IV in 4-6 equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin susceptible (minimum inhibitory concentration ≤0.1 μg/mL) and does not produce β-lactamase.

‡Gentamicin should be administered in close temporal proximity to vancomycin, nafcillin, or oxacillin dosing.

§Pediatric dose should not exceed that of a normal adult.

¶For specific dosing adjustment and issues concerning vancomycin, see Table 437-4 footnotes.

small" number of cases; and (3) the risk of antibiotic-related adverse events exceeds the benefits of prophylactic therapy. Improving general dental hygiene was felt to be a more important factor in reducing the risk of infective endocarditis resulting from routine daily bacteremias. The current recommendations limit the use of prophylaxis to those patients with cardiac conditions associated with the greatest risk of an adverse outcome from infective endocarditis (Table 437-6). Patients with permanently damaged valves from rheumatic heart disease should also be considered for prophylaxis. Prophylaxis for these patients is recommended for "all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa." Furthermore, "placement of removable prosthodontic or endodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth and bleeding from trauma to the lips or oral mucosa" are not indications for prophylaxis. Given that many invasive respiratory tract procedures do cause bacteremia, prophylaxis for many of these procedures is considered reasonable. In contrast to prior recommendations, prophylaxis for gastrointestinal or genitourinary procedures is no longer recommended in the majority of cases. Prophylaxis for patients undergoing cardiac surgery with placement of prosthetic material is still recommended. Given the highly individual nature of these recommendations and the continued concern amongst some cardiologists over their adoption, direct consultation with the child's cardiologist is still the best method for determining a specific patient's ongoing need for prophylaxis (Table 437-7).

Continuing education regarding both oral hygiene and, in appropriate cases, the need for prophylaxis is important, especially in teenagers

Table 437-6 2007 Statement of the American Heart Association (AHA): Cardiac Conditions Associated with the Highest Risk of an Adverse Outcome from Infective Endocarditis for Which Prophylaxis with Dental Procedures Is Reasonable

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis

CONGENITAL HEART DISEASE (CHD)*
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired CHD with prosthetic material or device, whether placed by surgery or catheter intervention, during the 1st 6 mo after the procedure†
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch, or prosthetic device (which inhibit endothelialization)
Cardiac transplantation recipients who develop cardiac valvulopathy

*Except for the conditions listed here, antibiotic prophylaxis is no longer recommended by the AHA for any other form of CHD.

†Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 mo after the procedure.

Chapter 438
Rheumatic Heart Disease
Daniel Bernstein

Rheumatic involvement of the valves is the most important sequelae of acute rheumatic fever (see Chapter 183.1). The valvular lesions begin as small verrucae composed of fibrin and blood cells along the borders of one or more of the heart valves. The mitral valve is affected most often, followed in frequency by the aortic valve; right-sided heart manifestations are rare. As the inflammation subsides, the verrucae tend to disappear and leave scar tissue. With repeated attacks of rheumatic fever, new verrucae form near the previous ones, and the mural endocardium and chordae tendineae become involved.

A single episode of acute rheumatic fever usually results in complete healing of valvular lesions while repeated episodes, especially on previously affected valves result in rheumatic heart disease. Diagnosing acute rheumatic fever requires the fulfillment of the Jones criteria (see Chapter 183.1), while the diagnosis of rheumatic heart disease is based on cardiac auscultation signs of mitral or aortic valve involvement, which may not detect early valve injury. Screening large populations at risk for rheumatic heart disease with echocardiography has demonstrated a substantially greater number of patients with rheumatic heart disease than those detected by auscultation (Fig. 438-1). If this is confirmed, it has important public health significance in that many more patients will need to receive prophylaxis to prevent further episodes of acute rheumatic fever and worsening of valve injury.

PATTERNS OF VALVULAR DISEASE
Mitral Insufficiency
Pathophysiology
Mitral insufficiency is the result of structural changes that usually include some loss of valvular substance and shortening and thickening of the chordae tendineae. During acute rheumatic fever with severe cardiac involvement, heart failure is caused by a combination of mitral insufficiency coupled with inflammatory disease of the pericardium, myocardium, endocardium, and epicardium. Because of the high volume load and inflammatory process, the left ventricle becomes enlarged. The left atrium dilates as blood regurgitates into this chamber. Increased left atrial pressure results in pulmonary congestion and symptoms of left-sided heart failure. Spontaneous improvement usually occurs with time, even in patients in whom mitral insufficiency is severe at the onset. The resultant chronic lesion is most often mild or moderate in severity, and the patient is asymptomatic. More than half of patients with acute mitral insufficiency no longer have the mitral murmur 1 yr later. In patients with severe chronic mitral insufficiency, pulmonary arterial pressure becomes elevated, the right ventricle and atrium become enlarged, and right-sided heart failure subsequently develops.

Clinical Manifestations
The physical signs of mitral insufficiency depend on its severity. With mild disease, signs of heart failure are not present, the precordium is quiet, and auscultation reveals a high-pitched holosystolic murmur at the apex that radiates to the axilla. With severe mitral insufficiency, signs of chronic heart failure may be noted. The heart is enlarged, with a heaving apical left ventricular impulse and often an apical systolic thrill. The 2nd heart sound may be accentuated if pulmonary hypertension is present. A 3rd heart sound is generally prominent. A holosystolic murmur is heard at the apex with radiation to the axilla. A short mid-diastolic rumbling murmur is caused by increased blood flow across the mitral valve as a result of the insufficiency. Auscultation of a diastolic murmur does not necessarily mean that mitral stenosis is present. The latter lesion takes many years to develop and is characterized by a diastolic murmur of greater length, usually with presystolic accentuation.

The electrocardiogram and chest x-rays are normal if the lesion is mild. With more severe insufficiency, the electrocardiogram shows prominent bifid P waves, signs of left ventricular hypertrophy, and associated right ventricular hypertrophy if pulmonary hypertension is present. Roentgenographically, prominence of the left atrium and ventricle can be seen. Congestion of perihilar vessels, a sign of pulmonary venous hypertension, may also be evident. Calcification of the mitral valve is rare in children. Echocardiography shows enlargement of the

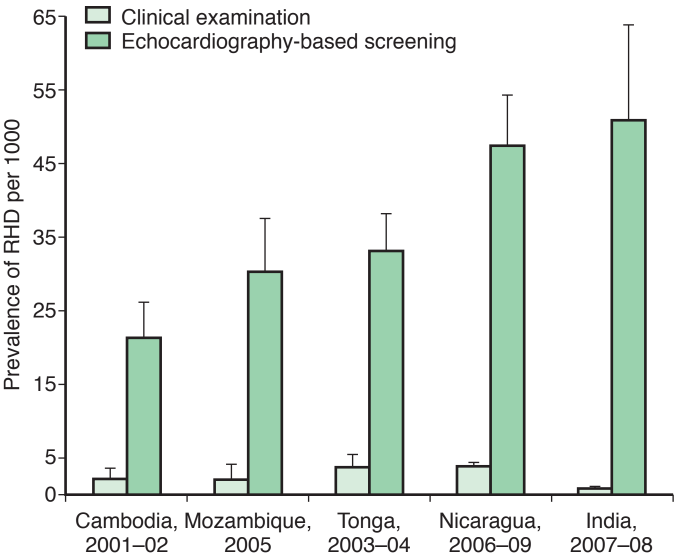

Figure 438-1 Rheumatic heart disease (RHD) prevalence rates in children: echocardiography-based screening versus clinical examination. Results of the first 4 studies to investigate differences in RHD detection methods are shown. In Cambodia and Mozambique, echocardiography-based RHD was defined as regurgitant jet seen in at least 2 planes and morphologic features suggestive of the disease, such as restricted leaflet mobility, focal or generalized valvular thickening, and abnormal subvalvular thickening. In Tonga, echocardiography-based RHD was defined by a combination of World Health Organization criteria (regurgitant jet >1 cm in length in at least 2 planes, mosaic color jet with a peak velocity >2.5 m/sec, persistence of jet throughout systole [mitral valve] and diastole [aortic valve], and morphologic criteria such as valvular thickening and elbow deformity of the anterior mitral valve leaflet). If only mitral regurgitation with no morphologic changes was seen, the case was considered as definite only if mitral regurgitation was graded at least as mild. Mitral or aortic stenoses were a sign of definite RHD, defined by a transmitral mean pressure gradient greater than 4 mm Hg and a transaortic peak velocity greater than 2 m/sec, respectively. If only very mild mitral regurgitation and no morphologic changes were seen, the child was classified as having borderline RHD (not reported here). In Nicaragua, echocardiography-based RHD, including possible cases, was defined by morphologic mitral changes (thickened mitral valve leaflets or dogleg deformity of the anterior mitral valve leaflet or both), and substantial left-side regurgitation (holosystolic mitral regurgitation jet ≥2 cm and ≥1 cm for aortic regurgitation, in 2 planes, of high velocity). In India, echocardiography-based RHD was defined by regurgitant jet greater than 1 cm in length in at least 2 planes, mosaic color jet with a peak velocity greater than 2.5 m/sec, and persistence of jet throughout systole (mitral valve) and diastole (aortic valve). Prevalence would only be 14.1 per 1000 with more stringent criteria combining Doppler echocardiography and pronounced mitral valve thickening (>6 mm). *(From Marijon E, Mirabel M, Celermajer DS, Jouven X: Rheumatic heart disease.* Lancet *379:953-964, 2012, Fig. 5.)*

left atrium and ventricle, an abnormally thickened mitral valve, and Doppler studies demonstrate the severity of the mitral regurgitation. Heart catheterization and left ventriculography are considered only if diagnostic questions are not totally resolved by noninvasive assessment.

Complications

Severe mitral insufficiency may result in cardiac failure that may be precipitated by progression of the rheumatic process, the onset of atrial fibrillation, or infective endocarditis. The effects of chronic mitral insufficiency may become manifest after many years and include right ventricular failure and atrial and ventricular arrhythmias.

Treatment

In patients with mild mitral insufficiency, prophylaxis against recurrences of rheumatic fever is all that is required. Treatment of complicating heart failure (see Chapter 442), arrhythmias (see Chapter 435), and infective endocarditis (see Chapter 437) is described elsewhere. Afterload-reducing agents (angiotensin-converting enzyme inhibitors or angiotensin receptor blockers) may reduce the regurgitant volume and preserve left ventricular function. Surgical treatment is indicated for patients who despite adequate medical therapy have persistent heart failure, dyspnea with moderate activity, and progressive cardiomegaly, often with pulmonary hypertension. Although annuloplasty provides good results in some children and adolescents, valve replacement may be required. In patients with a prosthetic mitral valve replacement, prophylaxis against bacterial endocarditis is warranted for dental procedures, as the routine antibiotics taken by these patients for rheumatic fever prophylaxis are insufficient to prevent endocarditis.

Mitral Stenosis

Pathophysiology

Mitral stenosis of rheumatic origin results from fibrosis of the mitral ring, commissural adhesions, and contracture of the valve leaflets, chordae, and papillary muscles over time. It usually takes 10 yr or more for the lesion to become fully established, although the process may occasionally be accelerated. Rheumatic mitral stenosis is seldom encountered before adolescence and is not usually recognized until adult life. Significant mitral stenosis results in increased pressure and enlargement and hypertrophy of the left atrium, pulmonary venous hypertension, increased pulmonary vascular resistance, and pulmonary hypertension. Right ventricular hypertrophy and right atrial dilation ensue and are followed by right ventricular dilation, tricuspid regurgitation, and clinical signs of right-sided heart failure.

Clinical Manifestations

Generally, the correlation between symptoms and the severity of obstruction is good. Patients with mild lesions are asymptomatic. More severe degrees of obstruction are associated with exercise intolerance and dyspnea. Critical lesions can result in orthopnea, paroxysmal nocturnal dyspnea, and overt pulmonary edema, as well as atrial arrhythmias. When pulmonary hypertension has developed, right ventricular dilation may result in functional tricuspid insufficiency, hepatomegaly, ascites, and edema. Hemoptysis caused by rupture of bronchial or pleurohilar veins and, occasionally, by pulmonary infarction may occur.

Jugular venous pressure is increased in severe disease with heart failure, tricuspid valve disease, or severe pulmonary hypertension. In mild disease, heart size is normal; however, moderate cardiomegaly is usual with severe mitral stenosis. Cardiac enlargement can be massive when atrial fibrillation and heart failure supervene. A parasternal right ventricular lift is palpable when pulmonary pressure is high. The principal auscultatory findings are a loud 1st heart sound, an opening snap of the mitral valve, and a long, low-pitched, rumbling mitral diastolic murmur with presystolic accentuation at the apex. The mitral diastolic murmur may be virtually absent in patients who are in significant heart failure. A holosystolic murmur secondary to tricuspid insufficiency may be audible. In the presence of pulmonary hypertension, the pulmonic component of the 2nd heart sound is accentuated. An early diastolic murmur may be caused by associated rheumatic aortic insufficiency or pulmonary valvular insufficiency secondary to pulmonary hypertension.

Electrocardiograms and roentgenograms are normal if the lesion is mild; as the severity increases, prominent and notched P waves and varying degrees of right ventricular hypertrophy become evident. Atrial fibrillation is a common late manifestation. Moderate or severe lesions are associated with roentgenographic signs of left atrial enlargement and prominence of the pulmonary artery and right-sided heart chambers; calcifications may be noted in the region of the mitral valve. Severe obstruction is associated with a redistribution of pulmonary blood flow so that the apices of the lung have greater perfusion (the reverse of normal). Echocardiography shows thickening of the mitral valve, distinct narrowing of the mitral orifice during diastole and left atrial enlargement. Doppler can estimate the transmitral pressure gradient. Cardiac catheterization quantitates the diastolic gradient across

the mitral valve, allows for the calculation of valve area, and assesses the degree of elevation of pulmonary arterial pressure.

Treatment

Intervention is indicated in patients with clinical signs and hemodynamic evidence of severe obstruction but before the severe manifestations outlined earlier. Surgical valvotomy or balloon catheter mitral valvuloplasty generally yields good results; valve replacement is avoided unless absolutely necessary. Balloon valvuloplasty is indicated for symptomatic, stenotic, pliable, noncalcified valves of patients without atrial arrhythmias or thrombi.

Aortic Insufficiency

In chronic rheumatic aortic insufficiency, sclerosis of the aortic valve results in distortion and retraction of the cusps. Regurgitation of blood leads to volume overload with dilation and hypertrophy of the left ventricle. Combined mitral and aortic insufficiency is more common than aortic involvement alone.

Clinical Manifestations

Symptoms are unusual except in severe aortic insufficiency. The large stroke volume and forceful left ventricular contractions may result in palpitations. Sweating and heat intolerance are related to excessive vasodilation. Dyspnea on exertion can progress to orthopnea and pulmonary edema; angina may be precipitated by heavy exercise. Nocturnal attacks with sweating, tachycardia, chest pain, and hypertension may occur.

The pulse pressure is wide with bounding peripheral pulses. Systolic blood pressure is elevated, and diastolic pressure is lowered. In severe aortic insufficiency, the heart is enlarged, with a left ventricular apical heave. A diastolic thrill may be present. The typical murmur begins immediately with the 2nd heart sound and continues until late in diastole. The murmur is heard over the upper and midleft sternal border with radiation to the apex and upper right sternal border. Characteristically, it has a high-pitched blowing quality and is easily audible in full expiration with the diaphragm of the stethoscope placed firmly on the chest and the patient leaning forward. An aortic systolic ejection murmur is frequent because of the increased stroke volume. An apical presystolic murmur **(Austin Flint murmur)** resembling that of mitral stenosis is sometimes heard and is a result of the large regurgitant aortic flow in diastole preventing the mitral valve from opening fully.

Chest x-rays show enlargement of the left ventricle and aorta. The electrocardiogram may be normal, but in advanced cases it reveals signs of left ventricular hypertrophy and strain with prominent P waves. The echocardiogram shows a large left ventricle and diastolic mitral valve flutter or oscillation caused by regurgitant flow hitting the valve leaflets. Doppler studies demonstrate the degree of aortic runoff into the left ventricle. Magnetic resonance angiography (MRA) can be useful in quantitating regurgitant volume. Cardiac catheterization is necessary only when the echocardiographic data are equivocal.

Prognosis and Treatment

Mild and moderate lesions are well tolerated. Unlike mitral insufficiency, aortic insufficiency does not regress. Patients with combined lesions during the episode of acute rheumatic fever may have only aortic involvement 1-2 yr later. Treatment consists of afterload reducers (angiotensin-converting enzyme inhibitors or angiotensin receptor blockers) and prophylaxis against recurrence of acute rheumatic fever. Surgical intervention (valve replacement) should be carried out well in advance of the onset of heart failure, pulmonary edema, or angina, when signs of decreasing myocardial performance become evident as manifested by increasing left ventricular dimensions on the echocardiogram. Surgery is considered when early symptoms are present, ST-T wave changes are seen on the electrocardiogram, or evidence of decreasing left ventricular ejection fraction is noted.

Tricuspid Valve Disease

Primary tricuspid involvement is rare after rheumatic fever. Tricuspid insufficiency is more common secondary to right ventricular dilation resulting from unrepaired left-sided lesions. The signs produced by tricuspid insufficiency include prominent pulsations of the jugular veins, systolic pulsations of the liver, and a blowing holosystolic murmur at the lower left sternal border that increases in intensity during inspiration. Concomitant signs of mitral or aortic valve disease, with or without atrial fibrillation, are frequent. In these cases, signs of tricuspid insufficiency decrease or disappear when heart failure produced by the left-sided lesions is successfully treated. Tricuspid valvuloplasty may be required in rare cases.

Pulmonary Valve Disease

Pulmonary insufficiency usually occurs on a functional basis secondary to pulmonary hypertension and is a late finding with severe mitral stenosis. The murmur (**Graham Steell murmur**) is similar to that of aortic insufficiency, but peripheral arterial signs (bounding pulses) are absent. The correct diagnosis is confirmed by two-dimensional echocardiography and Doppler studies.

Section 6

Diseases of the Myocardium and Pericardium

Chapter 439

Diseases of the Myocardium

Robert L. Spicer and Stephanie M. Ware

The extremely heterogeneous heart muscle diseases associated with structural remodeling and/or abnormalities of cardiac function (cardiomyopathy) are important causes of morbidity and mortality in the pediatric population. Several classification schemes have been formulated in an effort to provide logical, useful, and scientifically based etiologies for the cardiomyopathies. Insight into the molecular genetic basis of cardiomyopathies has increased exponentially and etiologic classification schemes continue to evolve.

Table 439-1 classifies the cardiomyopathies based on their anatomic (ventricular morphology) and functional pathophysiology. Dilated cardiomyopathy, the most common form of cardiomyopathy, is characterized predominantly by left ventricular dilation and decreased left ventricular systolic function (Fig. 439-1). Hypertrophic cardiomyopathy demonstrates increased ventricular myocardial wall thickness, normal or increased systolic function, and often, diastolic (relaxation) abnormalities (Table 439-2; Figs. 439-2 and 439-3). Restrictive cardiomyopathy is characterized by nearly normal ventricular chamber size and wall thickness with preserved systolic function, but dramatically impaired diastolic function leading to elevated filling pressures and atrial enlargement (Fig. 439-4). Arrhythmogenic right ventricular cardiomyopathy and left ventricular noncompaction are characterized by specific morphologic abnormalities and heterogeneous functional disturbances.

Table 439-1 Etiology of Pediatric Myocardial Disease

CARDIOMYOPATHY	
Dilated Cardiomyopathy (DCM)	
Neuromuscular diseases	Muscular dystrophies (Duchenne, Becker, limb girdle, Emery-Dreifuss, congenital muscular dystrophy, etc.), myotonic dystrophy, myofibrillar myopathy
Inborn errors of metabolism	Fatty acid oxidation disorders (trifunctional protein, VLCAD), carnitine abnormalities (carnitine transport, CPTI, CPTII), mitochondrial disorders (including Kearns-Sayre syndrome), organic acidemias (propionic acidemia)
Genetic mutations in cardiomyocyte structural apparatus	Familial or sporadic DCM
Genetic syndromes	Alstrom syndrome, Barth syndrome (phospholipid disorders)
Ischemic	Most common in adults
Chronic tachyarrhythmias	
Hypertrophic Cardiomyopathy (HCM)	
Inborn errors of metabolism	Mitochondrial disorders (including Friedreich ataxia, mutations in nuclear or mitochondrial genome), storage disorders (glycogen storage disorders, especially Pompe; mucopolysaccharidoses; Fabry disease; sphingolipidoses; hemochromatosis; Danon disease)
Genetic mutations in cardiomyocyte structural apparatus	Familial or sporadic HCM
Genetic syndromes	Noonan, Costello, cardiofaciocutaneous, Beckwith-Wiedemann syndrome
Infant of a diabetic mother	Transient hypertrophy
Restrictive Cardiomyopathy (RCM)	
Neuromuscular disease	Myofibrillar myopathies
Metabolic	Storage disorders
Genetic mutations in cardiomyocyte structural apparatus	Familial or sporadic RCM
Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC)	
Genetic mutations in cardiomyocyte structural apparatus	Familial or sporadic ARVC
LVNC	X-linked (Barth syndrome), autosomal dominant, autosomal recessive, mitochondrial inheritance, or sporadic LVNC
SECONDARY OR ACQUIRED MYOCARDIAL DISEASE	
Myocarditis (see also Table 439-3)	**Viral:** parvovirus B19, adenovirus, coxsackievirus A and B, echovirus, rubella, varicella, influenza, mumps, Epstein-Barr virus, cytomegalovirus, measles, poliomyelitis, smallpox vaccine, hepatitis C virus, human herpesvirus 6, HIV virus, or opportunistic infections **Rickettsial:** psittacosis, *Coxiella*, Rocky Mountain spotted fever, typhus **Bacterial:** diphtheria, mycoplasma, meningococcus, leptospirosis, Lyme disease, typhoid fever, tuberculosis, streptococcus, listeriosis **Parasitic:** Chagas disease, toxoplasmosis, *Loa loa, Toxocara canis,* schistosomiasis, cysticercosis, echinococcus, trichinosis **Fungal:** histoplasmosis, coccidioidomycosis, actinomycosis
Systemic inflammatory disease	SLE, infant of mother with SLE, scleroderma, Churg-Strauss vasculitis, rheumatoid arthritis, rheumatic fever, sarcoidosis, dermatomyositis, periarteritis nodosa, hypereosinophilic syndrome (Löffler syndrome), acute eosinophilic necrotizing myocarditis, giant cell myocarditis, Kawasaki disease
Nutritional deficiency	Beriberi (thiamine deficiency), kwashiorkor, Keshan disease (selenium deficiency)
Drugs, toxins	Doxorubicin (Adriamycin), cyclophosphamide, chloroquine, ipecac (emetine), sulfonamides, mesalazine, chloramphenicol, alcohol, hypersensitivity reaction, envenomations, irradiation, herbal remedy (blue cohosh)
Coronary artery disease	Kawasaki disease, medial necrosis, anomalous left coronary artery from the pulmonary artery, other congenital coronary anomalies (anomalous right coronary, coronary ostial stenosis), familial hypercholesterolemia
Hematology-oncology	Anemia, sickle cell disease, leukemia
Endocrine-neuroendocrine	Hyperthyroidism, carcinoid tumor, pheochromocytoma

CPTI/CPTII, carnitine palmitoyltransferase 1/2; LVNC, left ventricular noncompaction; SLE, systemic lupus erythematosus; VLCAD, very long chain acyl coenzyme A dehydrogenase.

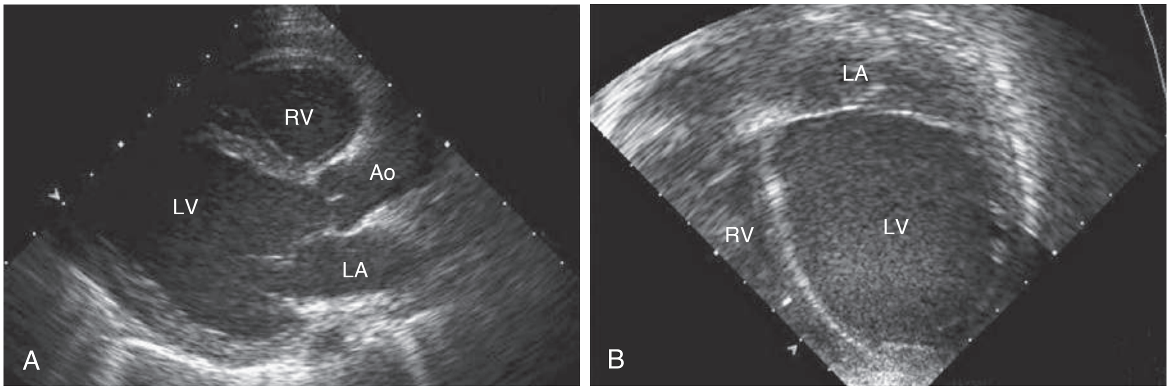

Figure 439-1 Echocardiogram of a patient with dilated cardiomyopathy. **A,** Parasternal long-axis view showing the enlarged left ventricle. **B,** Apical 4-chamber view showing the large left ventricle compressing the right ventricle. 439.1 Dilated Cardiomyopathy

Robert L. Spicer and Stephanie M. Ware

ETIOLOGY AND EPIDEMIOLOGY

Dilated cardiomyopathy (DCM), the most common form of cardiomyopathy in children, is the cause of significant morbidity and mortality as well as a common indication for cardiac transplantation. The etiologies are diverse. Unlike adult patients with DCM, ischemic etiologies are rare in children, although these include anomalous origin of the left coronary artery from the pulmonary artery, premature coronary atherosclerosis (homozygous type II hypercholesterolemia), and coronary inflammatory diseases, such as Kawasaki disease. It is estimated that up to 50% of cases are genetic (usually autosomal dominant; some

are autosomal recessive or X-linked), including some with metabolic causes (see Table 439-1). Although the most common etiology of DCM remains idiopathic, it is likely that undiagnosed familial/genetic conditions and myocarditis predominate. Associate features may include conduction defects or sensorineural hearing loss. The annual incidence of DCM in children younger than 18 yr is 0.57 cases per 100,000 per year. Incidence is higher in males, African-Americans, and in infants less than 1 yr old.

PATHOGENESIS

The pathogenesis of the ventricular dilation and altered contractility seen in DCM varies depending on the underlying etiology; systolic dysfunction and myocyte injury are common. Genetic abnormalities of several components of the cardiac muscle including sarcomere protein, the cytoskeleton, and the proteins that bridge the contractile apparatus to the cytoskeleton, have been identified in autosomal dominant and X-linked inherited disorders. DCM can occur following viral myocarditis and, although the primary pathogenesis varies from direct myocardial injury to viral-induced inflammatory injury, the resulting myocardial damage, ventricular enlargement, and poor function likely occur by a final common pathway similar to that which occurs in genetic disorders.

In 20-50% of cases, the DCM is familial with autosomal dominant inheritance most common (see Table 439-2). **Duchenne and Becker muscular dystrophies** (see Chapter 609.1) are X-linked cardiomyopathies that account for 5-10% of familial DCM cases. These dystrophinopathies result in an abnormal sarcomere–cytoskeleton connection, causing impaired myocardial force generation, myocyte damage/scarring, chamber enlargement, and altered function.

Mitochondrial myopathies, like the muscular dystrophies, may present clinically with a predominance of extracardiac findings and are inherited in a recessive or mitochondrial pattern. Disorders of **fatty acid oxidation** present with systemic derangements of metabolism (hypoketotic hypoglycemia, acidosis, and hepatic dysfunction), some with peripheral myopathy and neuropathy, and others with sudden death or life-threatening cardiac arrhythmias.

Anthracycline cardiotoxicity (doxorubicin [Adriamycin]) on rare occasion causes acute inflammatory myocardial injury, but more classically results in DCM and occurs in up to 30% of patients given a cumulative dose of doxorubicin exceeding 550 mg/m^2. The risk of toxicity appears to be exacerbated by concomitant radiation therapy.

CLINICAL MANIFESTATIONS

Although more prevalent in patients less than 1 yr of age, all age groups may be affected. Clinical manifestations of DCM are most commonly those of heart failure, but can also include palpitations, syncope, and sudden death. Irritability or lethargy can be accompanied by additional nonspecific complaints of failure to thrive, nausea, vomiting, or abdominal pain. Respiratory symptoms (tachypnea, wheezing, cough, or dyspnea on exertion) are often present. Uncommonly, patients may present acutely with pallor, altered mentation, hypotension, and shock. Patients can be tachycardic with narrow pulse pressure and have hepatic enlargement, and rales or wheezing. The precordial cardiac impulse is increased and the heart may be enlarged to palpation or percussion. Auscultation may reveal a gallop rhythm in addition to tachycardia and occasionally murmurs of mitral or, less commonly, tricuspid insufficiency may be present. The presence of hypoglycemia, acidosis, hypotonia, or signs of liver dysfunction suggests an inborn error of metabolism. Neurologic or skeletal muscle deficits are associated with mitochondrial disorders or muscular dystrophies.

LABORATORY FINDINGS

Electrocardiographic screening reveals atrial or ventricular hypertrophy, nonspecific T-wave abnormalities, and, occasionally, atrial or ventricular arrhythmias. The chest x-ray may demonstrate cardiomegaly and pulmonary vascular prominence or pleural effusions. The echocardiogram is often diagnostic, demonstrating the characteristic findings of left ventricular enlargement, decreased ventricular contractility, and occasionally a globular (remodeled) left ventricular contour (see Fig. 439-1). Right ventricular enlargement and depressed function are occasionally noted. Echo Doppler studies can reveal evidence of pulmonary hypertension, mitral regurgitation, or other structural cardiac or coronary abnormalities.

Additional testing should include complete blood count, renal and liver function tests, creatine phosphokinase, cardiac troponin I, lactate, brain natriuretic peptide, plasma amino acids, urine organic acids, and an acylcarnitine profile. Additional genetic and enzymatic testing may be useful (see Table 439-2). Cardiac catheterization and endomyocardial biopsy are not routine but may be useful in patients with acute DCM. Biopsy samples can be examined histologically for the presence of mononuclear cell infiltrates, myocardial damage, storage abnormalities, and for evidence of infection. It is considered standard of care to screen 1st-degree family members utilizing echocardiography and electrocardiogram (ECG) in idiopathic and familial cases of DCM.

PROGNOSIS AND MANAGEMENT

The 1 and 5 yr freedom from death or transplantation in patients diagnosed with DCM is 61% and 47%, respectively. Independent risk factors at DCM diagnosis for subsequent death or transplantation include older age, congestive heart failure, lower left ventricular fractional shortening *z* score, and underlying etiology. DCM is the most common cause for cardiac transplantation in pediatric and adult studies.

The therapeutic approach to patients with DCM includes a careful assessment to uncover possible treatable etiologies, screening of family members, and rigorous pharmacologic therapy. Decongestive therapy may improve symptoms of heart failure, prolong survival, and occasionally results in complete resolution of dysfunction. Patients are often treated with diuretics and angiotensin-converting enzyme inhibitors. The use of digitalis and angiotensin receptor blockers may be of additional benefit. β-Adrenergic blockade with carvedilol or metoprolol is often used in patients with chronic heart failure although pediatric specific outcome data have failed to show effectiveness. In patients presenting with extreme degrees of heart failure or circulatory collapse, intensive care measures are often required, including intravenous inotropes and diuretics, mechanic ventilatory support, and on occasion, mechanical circulatory support, which may include ventricular assist devices, extracorporeal membrane oxygenation, and ultimately cardiac transplantation. In patients with DCM and atrial or ventricular arrhythmias, specific antiarrhythmic therapy should be instituted.

Bibliography is available at Expert Consult.

439.2 Hypertrophic Cardiomyopathy

Robert L. Spicer and Stephanie M. Ware

ETIOLOGY AND EPIDEMIOLOGY

Hypertrophic cardiomyopathy (HCM) is a heterogeneous, relatively common, and potentially life-threatening form of cardiomyopathy. The causes of HCM are heterogeneous and include inborn errors of metabolism, neuromuscular disorders, syndromic conditions, and genetic abnormalities of the structural components of the cardiomyocyte (see Table 439-1). Both the age of onset and associated features are helpful in identifying the underlying etiology.

HCM is a genetic disorder and frequently occurs as a result of mutations in sarcomere or cytoskeletal components of the cardiomyocyte (see Fig. 439-2). Mutations of the genes encoding cardiac β-myosin heavy-chain *(MYH7)* and myosin-binding protein C *(MYBPC3)* are the most common (see Table 439-2). Mutations are inherited in an autosomal dominant pattern with widely variable penetrance; many cases represent de novo mutations. Some patients have mutations in more than 1 sarcomere or cytoskeletal gene and may manifest disease earlier and with more-severe symptoms. Additional genetic causes for HCM include nonsarcomeric protein mutations, such as the γ_2-regulatory subunit of adenosine monophosphate–activated protein kinase *(PRKAG2)* and the lysosome-associated membrane protein 2α-galactosidase (Danon disease, a form of glycogen storage disease). Syndromic conditions, such as Noonan syndrome, may present with

HCM at birth and recognition of extracardiac manifestations is important in making the diagnosis.

Glycogen storage disorders such as Pompe disease often present in infancy with a heart murmur, abnormal ECG, systemic signs and symptoms, and occasionally heart failure. The characteristic ECG in Pompe disease demonstrates prominent P waves, a short P-R interval, and massive QRS voltages; the echocardiogram confirms severe, often concentric, left ventricular hypertrophy.

PATHOGENESIS

HCM is characterized by the presence of increased left ventricular wall thickness in the absence of structural heart disease or hypertension. Often the interventricular septum is disproportionately involved, leading to the previous designation of idiopathic hypertrophic subaortic stenosis or the current term of asymmetric septal hypertrophy. In the presence of a resting or provokable outflow tract gradient, the term hypertrophic obstructive cardiomyopathy is used. Although the left ventricle is predominantly affected, the right ventricle may be involved, particularly in infancy. The mitral valve can demonstrate systolic anterior motion and mitral insufficiency. Left ventricular outflow tract obstruction occurs in 25% of patients, is dynamic in nature, and may in part be secondary to the abnormal position of the mitral valve as well as the obstructing subaortic hypertrophic cardiac muscle. The cardiac myofibrils and myofilaments demonstrate disarray and myocardial fibrosis.

Typically, systolic pump function is preserved or even hyperdynamic, though systolic dysfunction may occur late. Outflow tract obstruction with or without mitral insufficiency may be provoked by physiologic manipulations such as the Valsalva maneuver, positional changes, and physical activity. Frequently, the hypertrophic and fibrosed cardiac muscle demonstrates relaxation abnormalities (diminished compliance) and left ventricular filling may be impaired (diastolic dysfunction).

CLINICAL MANIFESTATIONS

Many patients are asymptomatic, and 50% of cases present with a heart murmur or during screening when another family member has been diagnosed with HCM. Symptoms of HCM may include palpitations, chest pain, easy fatigability, dyspnea, dizziness, and syncope. Sudden death is a well-recognized but uncommon manifestation that often occurs during physical exertion.

Characteristic physical examination findings include an overactive precordial impulse with a lift or heave, abnormal peripheral pulses (hyperdynamic or diminished), a systolic ejection murmur in the aortic region *not* associated with an ejection click, and an apical blowing murmur of mitral insufficiency.

DIAGNOSIS

The ECG typically demonstrates left ventricular hypertrophy with ST segment and T-wave abnormalities. Intraventricular conduction delays and signs of ventricular preexcitation (Wolff-Parkinson-White syndrome) may be present and should raise the possibility of Danon disease or Pompe disease. Chest radiography demonstrates normal or mildly increased heart size with a prominence of the left ventricle. Echocardiography is diagnostic in identifying, localizing, and quantifying the degree of myocardial hypertrophy (see Fig. 439-3). Doppler interrogation defines, localizes, and quantifies the degree of ventricular outflow tract obstruction and also demonstrates and quantifies the degree of mitral insufficiency. Diastolic dysfunction can be confirmed by M-mode, flow, and tissue Doppler techniques.

Cardiac catheterization may be indicated in some cases of HCM to define the left ventricular outflow gradient with and without pharmacologic provocation, to measure left ventricular diastolic pressures, to perform electrophysiologic testing of assessment of arrhythmia risk, or in rare cases, endomyocardial biopsy.

Additional diagnostic studies include metabolic testing, genetic testing for specific syndromes, or genetic testing for mutations in genes known to cause isolated HCM (see Table 439-2). The clinical availability of these tests is expanding. In adults, where isolated HCM is a common genetic diagnosis, it has been possible to identify a subset of mutations that confer an increased risk for arrhythmia or sudden death. As identification of the molecular basis of disease in children increases, similar correlations are expected to emerge. In addition, genetic diagnosis is useful to identify at-risk family members who require ongoing surveillance.

PROGNOSIS AND MANAGEMENT

Children under 1 yr of age or with inborn errors of metabolism or malformation syndromes or those with a mixed HCM/DCM have a significantly poorer prognosis. The risk of sudden death in older patients is greater in those with a history of cardiac arrest, ventricular tachycardia, exercise hypotension, syncope, excessive (>3 cm) ventricular wall thickness, and a ventricular obstruction gradient greater than 30 mm Hg. Although intrafamilial variability in symptoms occurs, a family history of sudden death is a highly significant predictor of risk.

Competitive sports and strenuous physical activity should be prohibited as most sudden deaths in patients with HCM occur during or immediately after vigorous physical exertion. β-adrenergic blocking agents (propranolol, atenolol) or calcium channel blocking agents (verapamil) may be useful in diminishing ventricular outflow tract obstruction, modifying ventricular hypertrophy, and improving ventricular filling. Although significant symptomatic improvement occurs in some patients, the risk for development of heart failure or sudden death has not been lessened. In patients with atrial or ventricular arrhythmias, specific antiarrhythmic therapy should be used. Patients with documented ventricular arrhythmias, strong family histories of arrhythmias or sudden death, or patients with syncope should be treated with an implantable cardioverter defibrillator.

Innovative interventional procedures to anatomically or physiologically reduce the degree of left ventricular outflow tract obstruction have been used. Dual-chamber pacing, alcohol septal ablation, surgical septal myomectomy, and mitral valve replacement have all met with some success.

First-degree relatives of patients identified as having HCM should be screened with electrocardiography and echocardiography. Genetic testing is available clinically. It is important to first test the affected individual in the family rather than "at-risk" individuals because 20-40% of cases of HCM will not demonstrate mutations in currently available panels of genes. If a causative mutation is identified, "at-risk" members of the family can be effectively tested. In families with HCM without demonstrable gene mutations, repeat noninvasive cardiac screening with ECG and echo should be undertaken in at risk individuals every 3-5 yr for patients younger than 12 yr of age and yearly throughout the teenage years and young adulthood. The clinical course of other affected family members and the results of genetic testing may be of some use in stratifying risk in an affected child.

Bibliography is available at Expert Consult.

439.3 Restrictive Cardiomyopathy

Robert L. Spicer and Stephanie M. Ware

ETIOLOGY AND EPIDEMIOLOGY

Restrictive cardiomyopathy (RCM) accounts for <5% of cardiomyopathy cases. Incidence increases with age, and is more common in females. In equatorial Africa, RCM accounts for a large number of deaths. Infiltrative myocardial causes and storage disorders frequently result in associated left ventricular hypertrophy and may represent HCM with restrictive physiology. Noninfiltrative causes include mutations in genes encoding sarcomeric or cytoskeletal proteins. Although there has been significant success in discovering new gene mutations causing RCM, the majority of are considered idiopathic.

PATHOGENESIS

RCM is characterized by normal ventricular chamber dimensions, normal myocardial wall thickness, and preserved systolic function. Dramatic atrial dilation can occur as a result of the abnormal myocardial compliance and high ventricular diastolic pressure. Autosomal

dominant inheritance has been demonstrated for families with mutations in sarcomeric and cytoskeletal genes.

CLINICAL MANIFESTATIONS

Abnormal ventricular filling, sometimes referred to as *diastolic heart failure,* is manifest in the systemic venous circulation with edema, hepatomegaly, or ascites. Elevation of left-sided filling pressures result in cough, dyspnea, or pulmonary edema. With activity, patients may experience chest pain, shortness of breath, syncope/near syncope, or even sudden death. Pulmonary hypertension and pulmonary vascular disease develop and may progress rapidly. Heart murmurs are typically absent, but a gallop rhythm may be prominent. In the presence of pulmonary hypertension, an overactive right ventricular impulse and pronounced pulmonary component of the second heart sound are present.

DIAGNOSIS

The characteristic electrocardiographic finding of prominent P waves is usually associated with normal QRS voltages and nonspecific ST and T-wave changes. Right ventricular hypertrophy occurs in patients with pulmonary hypertension. The chest x-ray may be normal or demonstrate a prominent atrial shadow and pulmonary vascular redistribution. The echocardiogram is often diagnostic, demonstrating normal-sized ventricles with preserved systolic function and dramatic enlargement of the atria (see Fig. 439-4). Flow and tissue Doppler interrogation reveal abnormal filling parameters. Differential diagnosis from constrictive pericarditis is critical, as the latter can be treated surgically. Magnetic resonance imaging may be necessary to demonstrate the thickened or calcified pericardium often present in constrictive pericardial disease.

PROGNOSIS AND MANAGEMENT

Pharmacologic treatment modalities are of limited use and the prognosis of patients with RCM is generally poor with often progressive clinical deterioration. Sudden death is a significant risk, with a 2-yr survival of 50%. When signs of heart failure exist, judicious use of diuretics can result in clinical improvement. As a result of the dramatic atrial enlargement, these patients are predisposed to the development of atrial tachyarrhythmias and thromboemboli. Antiarrhythmic agents may be necessary and anticoagulation with platelet inhibitors or Coumadin is indicated.

Cardiac transplantation is the treatment of choice in many centers for patients with RCM, and the results are excellent in patients without pulmonary hypertension, pulmonary vascular disease, or severe congestive heart failure.

Bibliography is available at Expert Consult.

439.4 Left Ventricular Noncompaction, Arrhythmogenic Right Ventricular Cardiomyopathy, and Endocardial Fibroelastosis

Robert L. Spicer and Stephanie M. Ware

Left ventricular noncompaction (LVNC) was initially believed to be a rare disorder found only in children, but is now known to affect individuals of all ages. LVNC is characterized by a distinctive trabeculated or spongy-appearing left ventricle (Fig. 439-5) commonly associated with left ventricular hypertrophy and/or dilation, and at times, systolic or diastolic dysfunction. LVNC may be isolated or associated with structural congenital cardiac defects. Patients may present with signs of heart failure, arrhythmias, syncope, sudden death, or as an asymptomatic finding during screening of family members.

Imaging studies using ultrasound or magnetic resonance can demonstrate the characteristic pattern of deeply trabeculated left ventricle myocardium, most characteristically within the apex of the left ventricle. ECG findings are nonspecific and include chamber hypertrophy, ST and T-wave changes, or arrhythmias. In some patients, preexcitation is

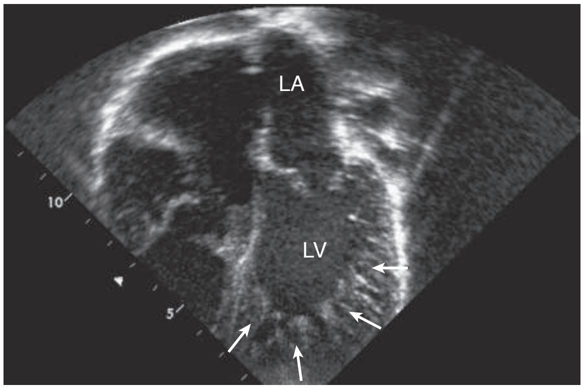

Figure 439-5 Echocardiogram of a patient with left ventricular noncompaction cardiomyopathy. Apical view showing the abnormal trabeculations of the left ventricle at the apex *(arrows).* For comparison, see the smooth walled LV in Figure 439-1. LA, left atrium; LV, left ventricle.

notable and giant QRS voltages occur in approximately 30% of younger children. Metabolic screening should be considered, especially in young children. Elevated serum lactate and urine 3-methylglutaconic acid may be seen in Barth syndrome, an X-linked disorder of phospholipid metabolism caused by a mutation in the tafazzin (*TAZ*) gene. Clinical testing for *TAZ* mutations is available and should be considered, especially in males. Patients with mitochondrial disorders frequently demonstrate signs of LVNC. These children are at risk for atrial or ventricular arrhythmias and thromboembolic complications. Treatment includes anticoagulation, antiarrhythmic therapy if needed, and treatment of heart failure if present. In patients refractory to medical therapy, cardiac transplantation has been used successfully.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is thought to be uncommon in North America but is among the most common forms of cardiomyopathy in Europe, especially Italy. Autosomal dominant inheritance is common. In addition, recessive forms associated with severe ARVC and skin manifestations are known. Comprehensive genetic screening has been reported to identify a cause in up to 50% of cases. ARVC is typically characterized by a dilated right ventricle with fibrofatty infiltration of the right ventricle wall; increasingly, left ventricle involvement is being recognized. Global and regional right and left ventricular dysfunction and ventricular tachyarrhythmias are the major clinical findings. Syncope or aborted sudden death can occur and should be treated with antiarrhythmic medications and placement of a defibrillator. In patients with ventricular dysfunction, heart failure management as indicated for patients with DCM may be of use.

Endocardial fibroelastosis (EFE), at one time an important cause of heart failure in children, is uncommon. The decline in primary EFE is likely related to the abolition of mumps virus infections by immunization practices. Rare familial cases exist, but the causative genes are unknown. Secondary EFE can occur with severe left-sided obstructive lesions such as aortic stenosis or atresia, hypoplastic left heart syndrome, or coarctation of the aorta. EFE is characterized by an opaque, white, fibroelastic thickening on the endocardial surface of the ventricle, which leads to systolic and/or diastolic dysfunction. Surgical removal of the endocardial fibrosis has been successfully utilized to improve cardiac function. Standard heart failure management including transplantation has been utilized in the management of EFE.

Data from Feldman AM, McNamara D: Myocarditis, N Engl J Med *343:1388–1398, 2000; Magnani JW, Dec GW: Myocarditis: current trends in diagnosis and treatment,* Circulation *113:876–990, 2006.*

degeneration and may be caused by infectious, connective tissue, granulomatous, toxic, or idiopathic processes. There may be associated systemic manifestations of the disease and on occasion the endocardium or pericardium is involved, though coronary pathology is uniformly absent. Patients may be asymptomatic, have nonspecific prodromal symptoms, or present with overt congestive heart failure, compromising arrhythmias, or sudden death. It is thought that viral infections are the most common etiology though myocardial toxins, drug exposures, hypersensitivity reactions, and immune disorders may also lead to myocarditis (Table 439-3).

ETIOLOGY AND EPIDEMIOLOGY

Viral Infections

Coxsackievirus and other enteroviruses, adenovirus, parvovirus, Epstein-Barr virus, parechovirus, influenza virus, and cytomegalovirus are the most common causative agents in children, though most known viral agents have been reported. In Asia, hepatitis C virus appears to be significant as well. The true incidence of viral myocarditis is unknown as mild cases probably go undetected. The disease is typically sporadic but may be epidemic. Manifestations are, to some degree, age dependent: in neonates and young infants, viral myocarditis can be fulminant; in children, it often will occur as an acute, myopericarditis with heart failure; and in older children and adolescents, it may present with signs and symptoms of acute or chronic heart failure or chest pain.

Bacterial Infections

Bacterial myocarditis has become far less common with the advent of advanced public health measures, which have minimized infectious causes such as diphtheria. Diphtheritic myocarditis (see Chapter 187) is unique as bacterial toxin may produce circulatory collapse and toxic myocarditis characterized by atrioventricular block, bundle-branch block, or ventricular ectopy. Any overwhelming systemic bacterial infection can manifest with circulatory collapse and shock with evidence of myocardial dysfunction characterized by tachycardia, gallop rhythm, and low cardiac output. Additional nonviral infectious causes of myocarditis include rickettsia, protozoa, parasitic infections, and fungal disease.

PATHOPHYSIOLOGY

Myocarditis is characterized by myocardial inflammation, injury or necrosis, and ultimately fibrosis. Cardiac enlargement and diminished systolic function occur as a direct result of the myocardial damage. Typical signs of congestive heart failure occur and may progress rapidly to shock, atrial or ventricular arrhythmias, and sudden death. Viral myocarditis may also become a chronic process with persistence of viral nucleic acid in the myocardium, and the perpetuation of chronic inflammation secondary to altered host immune response including activated T lymphocytes (cytotoxic and natural killer cells) and antibody-dependent cell mediated damage. Additionally, persistent viral infection may alter the expression of major histocompatibility complex antigens with resultant exposure of neoantigens to the immune system. Some viral proteins share antigenic epitopes with host cells, resulting in autoimmune damage to the antigenically related myocyte. Cytokines such as tumor necrosis factor-α and interleukin-1 are inhibitors of myocyte response to adrenergic stimuli and result in diminished cardiac function. The final result of viral-associated inflammation can be DCM.

CLINICAL MANIFESTATIONS

Manifestations of myocarditis range from asymptomatic or nonspecific generalized illness to acute cardiogenic shock and sudden death. Infants and young children more often have a fulminant presentation with fever, respiratory distress, tachycardia, hypotension, gallop rhythm, and cardiac murmur. Associated findings may include a rash or evidence of end organ involvement such as hepatitis or aseptic meningitis.

Patients with acute or chronic myocarditis may present with chest discomfort, fever, palpitations, easy fatigability, or syncope/near syncope. Cardiac findings include overactive precordial impulse, gallop rhythm, and an apical systolic murmur of mitral insufficiency.

In patients with associated pericardial disease, a rub may be noted. Hepatic enlargement, peripheral edema, and pulmonary findings such as wheezes or rales may be present in patients with decompensated heart failure.

DIAGNOSIS

Electrocardiographic changes are nonspecific and may include sinus tachycardia, atrial or ventricular arrhythmias, heart block, diminished QRS voltages, and nonspecific ST and T-wave changes, often suggestive of acute ischemia. Chest x-rays in severe, symptomatic cases reveal cardiomegaly, pulmonary vascular prominence, overt pulmonary edema, or pleural effusions. Echocardiography often shows diminished ventricular systolic function, cardiac chamber enlargement, mitral insufficiency, and occasionally, evidence of pericardial infusion.

Cardiac MRI is a standard imaging modality for the diagnosis of myocarditis; information on the presence and extent of edema, gadolinium-enhanced hyperemic capillary leak, myocyte necrosis, left ventricular dysfunction, and evidence of an associated pericardial effusion assist in the cardiac MRI diagnosis of myocarditis.

Endomyocardial biopsy may be useful in identifying inflammatory cell infiltrates or myocyte damage and performing molecular viral analysis using polymerase chain reaction techniques. Catheterization and biopsy, although not without risk (perforation and arrhythmias), should be performed by experienced personnel in patients suspected to have myocarditis or if there is strong suspicion for unusual forms of cardiomyopathy such as storage diseases or mitochondrial defects. Nonspecific tests include sedimentation rate, creatine phosphokinase isoenzymes, cardiac troponin I, and brain natriuretic peptide levels.

DIFFERENTIAL DIAGNOSIS

The predominant diseases mimicking acute myocarditis include carnitine deficiency, other metabolic disorders of energy generation, hereditary mitochondrial defects, idiopathic DCM, pericarditis, EFE, and anomalies of the coronary arteries (see Table 439-1).

TREATMENT

Primary therapy for acute myocarditis is supportive (see Chapter 442). Acutely, the use of inotropic agents, preferably milrinone, should be entertained but used with caution because of their proarrhythmic potential. Diuretics are often required as well. If in extremis, mechanical ventilatory support and mechanical circulatory support with ventricular assist device implantation or extracorporeal membrane oxygenation may be needed to stabilize the patient's hemodynamic status and serve as a bridge to recovery or cardiac transplantation. Diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers are of use in patients with compensated congestive heart failure in the outpatient setting but may be contraindicated in those presenting with fulminant heart failure and cardiovascular collapse. In patients manifesting with significant atrial or ventricular arrhythmias, specific antiarrhythmic agents (for example, amiodarone) should be administered and implantable cardioverter defibrillator placement considered.

Immunomodulation of patients with myocarditis is controversial. **Intravenous immune globulin** may have a role in the treatment of acute or fulminant myocarditis and **corticosteroids** have been reported to improve cardiac function, but the data are not convincing in children. Relapse has been noted in patients receiving immunosuppression who have been weaned from support. There are no studies to recommend specific antiviral therapies for myocarditis.

PROGNOSIS

The prognosis of symptomatic acute myocarditis in newborns is poor, and a 75% mortality has been reported. The prognosis is better for children and adolescents, although patients who have persistent evidence of DCM often progress to need for cardiac transplantation. Recovery of ventricular function has been reported in 10-50% of patients, however.

Chapter 440

Diseases of the Pericardium

Robert L. Spicer and Stephanie M. Ware

The heart is enveloped in a bilayer membrane, the pericardium, which normally contains a small amount of serous fluid. The pericardium is not vital to normal function of the heart, and primary diseases of the pericardium are uncommon. However, the pericardium may be affected by a variety of conditions (Table 440-1), often as a manifestation of a systemic illness and can result in serious, even life-threatening, cardiac compromise.

440.1 Acute Pericarditis

Robert L. Spicer and Stephanie M. Ware

PATHOGENESIS

Inflammation of the pericardium may have only minor pathophysiologic consequences in the absence of significant fluid accumulation in the pericardial space. When the amount of fluid in the nondistensible pericardial space becomes excessive, pressure within the pericardium increases and is transmitted to the heart resulting in impaired filling. Although small to moderate amounts of pericardial effusion can be well tolerated and clinically silent, once the noncompliant pericardium has been distended maximally, any further fluid accumulation causes abrupt impairment of cardiac filling and is termed cardiac tamponade. When untreated, tamponade can lead to shock and death. Pericardial effusions may be serous/transudative, exudative/purulent, fibrinous, or hemorrhagic.

Table 440-1	Etiology of Pericardial Disease
CONGENITAL Absence (partial, complete) Cysts Mulibrey nanism (*TRIM 37* gene mutation) Camptodactyly-arthropathy-coxa vara-pericarditis syndrome (*PRG4* gene mutation)	
INFECTIOUS Viral (coxsackievirus B, Epstein-Barr virus, influenza, adenovirus, parvovirus, HIV, mumps) Bacterial (*Haemophilus influenzae*, streptococcus, pneumococcus, staphylococcus, meningococcus, mycoplasma, tularemia, listeria, leptospirosis, tuberculosis, Q-fever, salmonella) Immune complex (meningococcus, *H. influenzae*) Fungal (actinomycosis, histoplasmosis) Parasitic (toxoplasmosis, echinococcosis)	
NONINFECTIOUS Idiopathic Systemic inflammatory diseases (acute rheumatic fever, juvenile idiopathic arthritis, systemic lupus erythematosus, mixed connective tissue disorders, systemic sclerosis, Kawasaki disease, Churg-Strauss syndrome, Behçet syndrome, sarcoidosis, familial Mediterranean fever and other recurrent fever syndromes, pancreatitis, granulomatosis with polyangiitis) Metabolic (uremia, hypothyroidism, Gaucher disease, very-long-chain acyl-CoA dehydrogenase deficiency) Traumatic (surgical, catheter, blunt) Lymphomas, leukemia, radiation therapy Primary pericardial tumors	

CLINICAL MANIFESTATIONS

The most common symptom of acute pericarditis is chest pain, typically described as sharp/stabbing, positional, radiating, worse with inspiration, and relieved by sitting upright or prone. Cough, fever, dyspnea, abdominal pain, and vomiting are nonspecific symptoms associated with pericarditis. Additionally, signs and symptoms of organ system involvement may occur in the presence of generalized systemic disease.

Muffled or distant heart sounds, tachycardia, narrow pulse pressure, jugular venous distention, and a pericardial friction rub provide clues to the diagnosis of acute pericarditis. Cardiac tamponade is recognized by the excessive fall of systolic blood pressure (>10 mm Hg) with inspiration. This pulsus paradoxus can be assessed by careful auscultatory blood pressure determination (automated blood pressure cuffs are inadequate), arterial pressure line wave form, or pulse oximeter tracing inspection. Conditions other than cardiac tamponade, which may result in pulsus paradoxus include severe dyspnea, obesity, and positive pressure ventilator support.

DIAGNOSIS

The electrocardiogram is often abnormal in acute pericarditis although the findings are nonspecific. Low voltage QRS amplitude may be seen as a result of pericardial fluid accumulation. Tachycardia and abnormalities of the ST segments, PR segments, and T waves may be present as well.

Although the chest x-ray findings in a patient with pericarditis without effusion are usually normal, in the presence of a significant effusion, cardiac enlargement will be seen and cardiac contour may be unusual (Erlenmeyer flask or water bottle appearance) (Fig. 440-1). Echocardiography is the most sensitive technique for identifying the size and location of a pericardial effusion. Compression and collapse of the right atrium and/or right ventricle are present with cardiac tamponade (Fig. 440-2). Abnormal diastolic filling parameters have also been described in cases of tamponade.

DIFFERENTIAL DIAGNOSIS

Chest pain similar to that present in pericarditis can occur with lung diseases, especially pleuritis, and with gastroesophageal reflux. Pain related to myocardial ischemia is usually more severe, more prolonged, and occurs with exercise, allowing distinction from pericarditis-induced pain. The presence of a pericardial effusion by echocardiography is virtually diagnostic of pericarditis.

Figure 440-1 Water bottle silhouette. This chest radiograph shows marked cardiomegaly, also known as a water bottle silhouette, which is seen in the presence of large pericardial effusions. Also note the associated pulmonary edema from associated high left atrial and left ventricular filling pressures. *(Courtesy of Dr. Steven M. Selbst, Wilmington, DE; from Durani Y, Giordani K, Goudie BW: Myocarditis and pericarditis in children.* Pediatr Clin North Am *57:1281–1303, 2010, Fig 7.)*

Infectious Pericarditis

A number of viral agents are known to cause pericarditis, and the clinical course of the majority of these infections is mild and spontaneously resolving. The term acute benign pericarditis is synonymous for viral pericarditis. Agents identified as causing pericarditis include the enteroviruses, influenza, adenovirus, respiratory syncytial virus, and parvovirus. As the course of this illness is usually benign, symptomatic treatment with nonsteroidal antiinflammatory agents is often sufficient. Patients with large effusions and tamponade may require pericardiocentesis. Presumed viral but often idiopathic pericarditis may have an autoimmune component. In up to 30%, there may be recurrences of pericarditis. Treatment and/or prevention of recurrences with colchicine improve symptoms and avoid recurrences in most of these patients. Patients with idiopathic recurrent pericarditis may also respond to treatment with anakinra. If the condition becomes chronic or relapsing, surgical pericardiectomy or creation of a pericardial window may be necessary.

Echocardiography is useful in differentiating pericarditis from myocarditis, the latter of which will show evidence of diminished myocardial contractility or valvular dysfunction. Pericarditis and myocarditis may occur together in some cases of viral infection.

Purulent pericarditis, often caused by bacterial infections, has become much less common with the advent of new immunizations for haemophilus and pneumococcal disease. Historically, purulent pericarditis was seen in association with severe pneumonias, epiglottitis, meningitis, or osteomyelitis. Patients with purulent pericarditis are acutely ill. Unless the infection is recognized and treated expeditiously, the course can be fulminant, leading to tamponade and death. Tuberculous pericarditis is rare in developed countries, but can be seen as a relatively common complication of HIV infection in regions where tuberculosis is endemic and access to antiretroviral therapy is limited. Immune-complex mediated pericarditis is a rare complication that may result in a nonpurulent (sterile) effusion following systemic bacterial infections such as meningococcus or haemophilus.

Noninfectious Pericarditis

Systemic inflammatory diseases including autoimmune, rheumatologic, and connective tissue disorders may involve the pericardium and result in serous pericardial effusions. Pericardial inflammation may be a component of the type II hypersensitivity reaction seen in patients with acute rheumatic fever. It is often associated with rheumatic valvulitis and responds quickly to antiinflammatory agents including steroids. Tamponade is very uncommon (see Chapters 183.1 and 438).

Juvenile idiopathic arthritis, usually systemic onset disease, can manifest with pericarditis. Differentiating rheumatoid pericardial inflammation from that seen with systemic lupus erythematosus is difficult and requires careful rheumatologic evaluation. Aspirin and/or corticosteroids can result in rapid resolution of a pericardial effusion but may be needed on a chronic basis to prevent relapse. Many of the autoinflammatory recurrent fever syndromes present with pericarditis, usually with other manifestations of those disorders (Chapter 163).

Patients with chronic renal failure or hypothyroidism may have pericardial effusions and should be carefully screened with physical exam, and, if indicated, imaging studies, during the course of their illness should clinical suspicion arise.

Especially common in referral centers with hematology/oncology units is the presence of pericardial effusion related to neoplastic disease. Conditions resulting in effusion include Hodgkin disease, lymphomas, and leukemia. Radiation therapy directed to the mediastinum of patients with malignancy can result in pericarditis and later constrictive pericardial disease.

The postpericardiotomy syndrome occurs in patients having undergone cardiac surgery and is characterized by fever, lethargy, anorexia, irritability, and chest/abdominal discomfort beginning 7-14 days postoperatively. There can be associated pleural effusions and serologic evidence of elevated antiheart antibodies. Postpericardiotomy syndrome is effectively treated with aspirin, nonsteroidal inflammatory

agents, and in severe cases, corticosteroids. Pericardial drainage is necessary in those patients with cardiac tamponade.

440.2 Constrictive Pericarditis

Robert L. Spicer and Stephanie M. Ware

Rarely, chronic pericardial inflammation can result in fibrosis, calcification, and thickening of the pericardium. Pericardial scarring may lead to impaired cardiac distensibility and filling and is termed constrictive pericarditis. Constrictive pericarditis can occur following recurrent or chronic pericarditis, cardiac surgery, or radiation to the mediastinum as a treatment for malignancies, most commonly Hodgkin disease or lymphoma.

Clinical manifestations of systemic venous hypertension predominate in cases of restrictive pericarditis. Jugular venous distention, peripheral edema, hepatomegaly, and ascites may precede signs of more significant cardiac compromise such as tachycardia, hypotension, and pulsus paradoxus. A pericardial knock, rub, and distant heart sounds might be present on auscultation. Abnormalities of liver function tests, hypoalbuminemia, hypoproteinemia, and lymphopenia may be present. On occasion, x-rays of the chest demonstrate calcifications of the pericardium.

Constrictive pericarditis may be difficult to distinguish clinically from restrictive cardiomyopathy as both conditions result in impaired myocardial filling (see Chapter 439.3). Echocardiography may be helpful in distinguishing constrictive pericardial disease from restrictive cardiomyopathy, but magnetic resonance imaging and computed tomographic imaging are more sensitive in detecting abnormalities of the pericardium. In rare instances, exploratory thoracotomy with direct examination of the pericardium may be required to confirm the diagnosis.

Although acute pericardial constriction is reported to respond to antiinflammatory agents, the more typical chronic constrictive pericarditis will respond only to surgical pericardiectomy with extensive resection of the pericardium.

Chapter 441
Tumors of the Heart
Robert L. Spicer and Stephanie M. Ware

Although cardiac tumors occur rarely in pediatric patients, they may result in serious hemodynamic or electrophysiologic abnormalities depending on tumor type and location.

The vast majority of tumors originating from the heart are benign. **Rhabdomyomas** are the most common pediatric cardiac tumors and are associated with tuberous sclerosis in 70-95% of cases (see Chapter 596.2). Rhabdomyomas may occur at any age, from fetal life through late adolescence. They are often multiple, can occur in any cardiac chamber, and originate within the myocardium extending, often, into the atrial or ventricular cavities (Fig. 441-1). Depending on their location and size, they can result in inflow or outflow obstruction leading to cyanosis or cardiac failure; many are asymptomatic. Atrial and ventricular arrhythmias have been reported with rhabdomyomas, and on occasion, ventricular preexcitation (Wolff-Parkinson-White) is present on electrocardiogram.

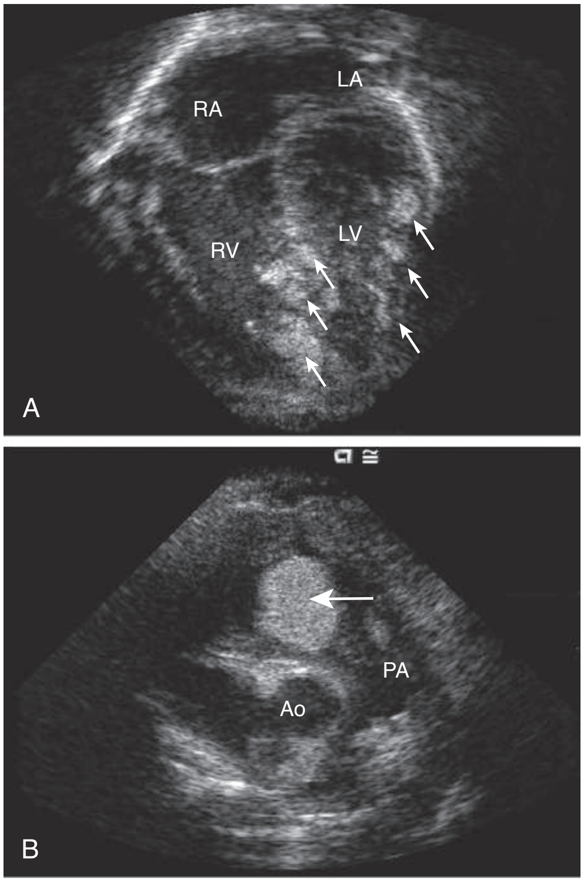

Figure 441-1 Echocardiograms demonstrating rhabdomyomas. **A,** Apical 4-chamber view showing multiple rhabdomyomas *(arrows)* within the septum and left ventricular myocardium. **B,** Short-axis view showing a large rhabdomyoma *(arrow)* extending into the right ventricular outflow tract. Ao, ascending aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Fibromas are the second most common pediatric cardiac tumor, and in contrast to rhabdomyomas, are usually solitary and intramyocardial. They can, by size and location, lead to heart failure, cyanosis, or rhythm disturbances. Loss of the tumor suppressor *PTCH1* is associated with the development of cardiac fibromas in sporadic cases. There is an increased incidence in patients with **Gorlin syndrome** (3%).

Myxomas, the most common cardiac tumor seen in adults, are infrequent in the pediatric population. Myxomas are predominantly intraatrial, appear pedunculated, and are rather mobile. They may cause obstruction to inflow or outflow and may present with a murmur, heart failure, or syncope. On occasion, atrial myxomas are associated with systemic symptoms of fever, malaise, and arthralgia. **Carney complex** is a familial autosomal dominant multiple neoplasia (often endocrine: pituitary adenoma, thyroid, testis, ovarian) and lentiginosis syndrome in which cardiac myxomas can occur at a young age in any or all cardiac chambers. *PRKAR1A* is the gene mutation in some families.

Other benign tumors include hemangiomas, Purkinje cell tumors, papillomas, lipomas, and mesotheliomas. Depending on their location, these benign tumors can result in valvular function abnormalities, myocardial dysfunction, or heart block and other arrhythmias.

Malignant pediatric cardiac tumors are far less common than benign tumors (75% vs. 25%), and the vast majority of such malignancies are sarcomas including angiosarcomas, rhabdosarcomas, or fibrosarcomas. Lymphomas and pheochromocytomas are reported but rare. Tumors originating from noncardiac sources that invade, extend, or metastasize to the heart are more commonly seen than primary malignant cardiac tumors. In pediatric patients, Wilms tumor and lymphoma/leukemia are the most common causes of such secondary tumors.

Although the manifestations of cardiac tumors in pediatric patients are protean, when a tumor is suspected, noninvasive imaging with echocardiography and/or magnetic resonance imaging may be diagnostic and can determine tumor type, location, extent, and hemodynamic impact. Electrocardiogram and Holter studies are valuable adjuncts when rhythm abnormalities are suspected. Cardiac catheterization is rarely indicated, but may be utilized to confirm tumor location, assess intracardiac hemodynamics, and perform biopsy for histologic assessment. Risks including blood loss, perforation, arrhythmia, and vessel injury should be considered when discussing catheterization and biopsy.

Because the natural history of rhabdomyomas is one of spontaneous diminution or complete resolution, treatment of the majority of cardiac tumors in pediatric patients is usually unnecessary. Everolimus, an inhibitor of the mammalian target of rapamycin, may enhance resolution in symptomatic patients with cardiac rhabdomyomas. Careful clinical follow-up and imaging are important. Antiarrhythmic medications may be prescribed to control rhythm disorders. Surgical removal of a cardiac tumor may be indicated to relieve obstruction, improve myocardial or valve function, or control arrhythmias. Heart transplantation has been performed in cases of unresectable tumors with significant hemodynamic compromise. Wilms tumors extending from the inferior vena cava into the atrium may require cardiopulmonary bypass support during the course of primary resection of the renal tumor. Radiation or chemotherapy can improve cardiac function in rare cases of lymphoma or leukemia compressing the heart with hemodynamic compromise.

Section 7

Cardiac Therapeutics

Chapter 442

Heart Failure

Daniel Bernstein

Heart failure occurs when the heart cannot deliver adequate cardiac output to meet the metabolic needs of the body. In the early stages of heart failure, various compensatory mechanisms are evoked to maintain normal metabolic function. When these mechanisms become ineffective, increasingly severe clinical manifestations result (see Chapter 70).

PATHOPHYSIOLOGY

The heart can be viewed as a pump with an output proportional to its filling volume and inversely proportional to the resistance against which it pumps. As ventricular end-diastolic volume increases, a healthy heart increases cardiac output until a maximum is reached and cardiac output can no longer be augmented (the Frank-Starling principle; Fig. 442-1). The increased stroke volume obtained in this manner is a result of stretching of myocardial fibers, but it also results in increased wall tension, which elevates myocardial oxygen consumption. Hearts working under various types of stress function along different Frank-Starling curves. Cardiac muscle with compromised intrinsic contractility requires a greater degree of dilation to produce increased stroke volume and does not achieve the same maximal

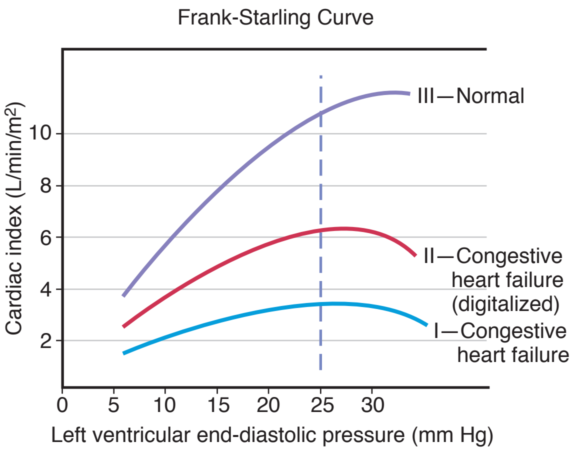

Figure 442-1 **The Frank-Starling relationship.** As left ventricular end-diastolic (LVED) pressure increases, the cardiac index increases, even in the presence of congestive heart failure, until a critical level of LVED pressure is reached. Adding an inotropic agent (digoxin) shifts the curve from I to II. *(From Gersony WM, Steep CN. In Dickerman JD, Lucey JF, editors:* Smith's The critically ill child: diagnosis and medical management, *ed 3, Philadelphia, 1984, WB Saunders.)*

cardiac output as normal myocardium does. If a cardiac chamber is already dilated because of a lesion causing increased preload (e.g., a left-to-right shunt or valvular insufficiency), there is little room for further dilation as a means of augmenting cardiac output. The presence of lesions that result in increased afterload to the ventricle (aortic or pulmonic stenosis, coarctation of the aorta) decreases cardiac performance, thereby resulting in a depressed Frank-Starling relationship.

Systemic oxygen transport is calculated as the product of cardiac output and systemic oxygen content. **Cardiac output** can be calculated as the product of heart rate and stroke volume. The primary determinants of stroke volume are the afterload (pressure work), preload (volume work), and contractility (intrinsic myocardial function). Abnormalities in heart rate can also compromise cardiac output; for example, tachyarrhythmias shorten the diastolic time interval for ventricular filling. Alterations in the oxygen-carrying capacity of blood (e.g., anemia or hypoxemia) also lead to a decrease in systemic oxygen transport and, if compensatory mechanisms are inadequate, can result in decreased delivery of substrate to tissues.

In some cases of heart failure, cardiac output is normal or increased, yet because of decreased systemic oxygen content (secondary to anemia) or increased oxygen demands (secondary to hyperventilation, hyperthyroidism, or hypermetabolism), an inadequate amount of oxygen is delivered to meet the body's needs. This condition, high-output failure, results in the development of signs and symptoms of heart failure when there is no basic abnormality in myocardial function and cardiac output is greater than normal. It is also seen with large systemic arteriovenous fistulas. These conditions reduce peripheral vascular resistance and cardiac afterload and increase myocardial contractility. Heart "failure" results when the demand for cardiac output exceeds the ability of the heart to respond. Chronic severe high-output failure may eventually result in a decrease in myocardial performance as the metabolic requirements of the myocardium are not met.

There are multiple systemic compensatory mechanisms used by the body to adapt to chronic heart failure. Some are mediated at the molecular/cellular level, such as upregulation or downregulation of various metabolic pathway components leading to changes in efficiency of oxygen and other substrate utilization. Others are mediated by neurohormones such as the renin–angiotensin system and the sympathoadrenal axis. One of the principal mechanisms for increasing cardiac output is an increase in sympathetic tone secondary to increased secretion of circulating epinephrine by the adrenals and increased release of norepinephrine at the neuromuscular junction. The initial beneficial effects of sympathetic stimulation include an increase in heart rate and myocardial contractility, mediated by these hormones' action on cardiac β-adrenergic receptors, increasing cardiac output. These hormones also cause vasoconstriction, mediated by their action on peripheral arterial α-adrenergic receptors. Some vascular beds may constrict more readily than others, so that blood flow is redistributed from the cutaneous, visceral, and renal beds to the heart and brain. Whereas these acute effects are beneficial, chronically increased sympathetic stimulation can have deleterious effects, including hypermetabolism, increased afterload, arrhythmogenesis, and increased myocardial oxygen requirements. Peripheral vasoconstriction can result in decreased renal, hepatic, and gastrointestinal tract function. Chronic exposure to circulating catecholamines leads to a decrease in the number of cardiac β-adrenergic receptors (downregulation) and also causes direct myocardial cell damage. Thus, therapeutic agents for heart failure are directed at restoring balance to these neuroendocrine systems.

CLINICAL MANIFESTATIONS

The clinical manifestations of heart failure depend in part on the degree of the child's cardiac reserve. A critically ill infant or child who has exhausted the compensatory mechanisms to the point that cardiac output is no longer sufficient to meet the basal metabolic needs of the body will be symptomatic at rest. Other patients may be comfortable when quiet but are incapable of increasing cardiac output in response to even mild activity without experiencing significant symptoms. Conversely, it may take rather vigorous exercise to compromise cardiac function in children who have less severe heart disease. A thorough history is extremely important in making the diagnosis of heart failure and in evaluating the possible causes. Parents who observe their child on a daily basis may not recognize subtle changes that have occurred over the course of days or weeks. Gradually worsening perfusion or increasing respiratory effort may not be recognized as an abnormal finding. Edema may be passed off as normal weight gain, and exercise intolerance as lack of interest in an activity. The history of a young infant should also focus on feeding (see Chapter 416). An infant with heart failure often takes less volume per feeding, becomes dyspneic while sucking, and may perspire profusely. Eliciting a history of fatigue in an older child requires detailed questions about activity level and its course over several months.

In children, the signs and symptoms of heart failure may be similar to those in adults and include fatigue, effort intolerance, anorexia, dyspnea, and cough. Many children, however, especially adolescents, may have primarily abdominal symptoms (abdominal pain, nausea, anorexia) and a surprising lack of respiratory complaints. Attention to the cardiovascular system may come only after an abdominal roentgenogram unexpectedly catches the lower end of an enlarged heart. The elevation in systemic venous pressure may be gauged by clinical assessment of jugular venous pressure and liver enlargement. Orthopnea and basilar rales are variably present; edema is usually discernible in dependent portions of the body, or anasarca may be present. Cardiomegaly is invariably noted. A gallop rhythm is common; when ventricular dilation is advanced, the holosystolic murmur of mitral or tricuspid valve regurgitation may be heard.

In infants, heart failure may be difficult to distinguish from other causes of respiratory distress. Prominent manifestations include tachypnea, feeding difficulties, poor weight gain, excessive perspiration, irritability, weak cry, and noisy, labored respirations with intercostal and subcostal retractions, as well as flaring of the alae nasi. The signs of cardiac-induced pulmonary congestion may be indistinguishable from those of bronchiolitis; wheezing is often a more prominent finding in young infants with heart failure than rales. Pneumonitis with or without atelectasis is common, especially in the right middle and lower lobes, a result of bronchial compression by the enlarged heart. Hepatomegaly usually occurs, and cardiomegaly is invariably present. In spite of pronounced tachycardia, a gallop rhythm can frequently be recognized. The other auscultatory signs are those produced by the underlying cardiac lesion. Clinical assessment of jugular venous pressure in infants may be difficult because of the shortness of the neck and the difficulty of observing a relaxed state; palpation of an enlarged

Table 442-1	Etiology of Heart Failure
FETAL Severe anemia (hemolysis, fetal-maternal transfusion, parvovirus B19–induced anemia, hypoplastic anemia) Supraventricular tachycardia Ventricular tachycardia Complete heart block Severe Ebstein anomaly or other severe right-sided lesions Myocarditis	
PREMATURE NEONATE Fluid overload Patent ductus arteriosus Ventricular septal defect Cor pulmonale (bronchopulmonary dysplasia) Hypertension Myocarditis Genetic cardiomyopathy	
FULL-TERM NEONATE Asphyxial cardiomyopathy Arteriovenous malformation (vein of Galen, hepatic) Left-sided obstructive lesions (coarctation of aorta, hypoplastic left heart syndrome) Large mixing cardiac defects (single ventricle, truncus arteriosus) Myocarditis Genetic cardiomyopathy	
INFANT-TODDLER Left-to-right cardiac shunts (ventricular septal defect) Hemangioma (arteriovenous malformation) Anomalous left coronary artery Genetic or metabolic cardiomyopathy Acute hypertension (hemolytic-uremic syndrome) Supraventricular tachycardia Kawasaki disease Myocarditis	
CHILD-ADOLESCENT Rheumatic fever Acute hypertension (glomerulonephritis) Myocarditis Thyrotoxicosis Hemochromatosis-hemosiderosis Cancer therapy (radiation, doxorubicin) Sickle cell anemia Endocarditis Cor pulmonale (cystic fibrosis) Genetic or metabolic cardiomyopathy (hypertrophic, dilated)	

liver is a more reliable sign. Edema may be generalized and usually involves the eyelids as well as the sacrum and less often the legs and feet. The differential diagnosis is age dependent (Table 442-1).

DIAGNOSIS

X-rays of the chest show cardiac enlargement. Pulmonary vascularity is variable and depends on the cause of the heart failure. Infants and children with large left-to-right shunts have exaggeration of the pulmonary arterial vessels to the periphery of the lung fields, whereas patients with cardiomyopathy may have a relatively normal pulmonary vascular bed early in the course of disease. Fluffy perihilar pulmonary markings suggestive of venous congestion and acute pulmonary edema are seen only with more severe degrees of heart failure. Cardiac enlargement is often noted as an unexpected finding on a chest roentgenogram performed to evaluate for a possible pulmonary infection, bronchiolitis, or asthma.

Chamber hypertrophy noted by electrocardiography may be helpful in assessing the cause of heart failure but does not establish the diagnosis. In cardiomyopathies, left or right ventricular ischemic changes may correlate with other noninvasive parameters of ventricular function. Low-voltage QRS morphologic characteristics with ST-T–wave abnormalities may also suggest myocardial inflammatory disease, but can be seen with pericarditis as well. The electrocardiogram is the best tool for evaluating rhythm disorders as a potential cause of heart failure, especially tachyarrhythmias.

Echocardiography is the standard technique for assessing ventricular function. The most commonly used parameter in children is fractional shortening (a single dimensional variable), determined as the difference between end-systolic and end-diastolic diameter divided by end-diastolic diameter. Normal fractional shortening is between approximately 28% and 42%. In adults, the most commonly used parameter is ejection fraction (which uses 2-dimensional data to calculate a 3-dimensional volume) and the normal range is 55-65%. In children with right ventricular enlargement or other cardiac pathology resulting in flattening of the interventricular septum, ejection fraction is used because fractional shortening measured in the standard echocardiographic short-axis view will not be accurate. Doppler studies can also be used to estimate cardiac output. Doppler assessment of transmitral flow can also be used as a noninvasive assessment of diastolic function. Doppler tissue imaging can assess not only cardiac function, but wall motion abnormalities that can interfere with normal synchronous cardiac contraction. Magnetic resonance angiography is also very useful in quantifying left and right ventricular function, volume and mass as well as coronary artery anatomy. If valvar regurgitation is present, magnetic resonance angiography can quantify the regurgitant fraction.

Arterial oxygen levels may be decreased when ventilation–perfusion inequalities occurs secondary to pulmonary edema. When heart failure is severe, respiratory or metabolic acidosis, or both, may be present. Infants with heart failure often display hyponatremia as a result of renal water retention. Chronic diuretic treatment can decrease serum sodium levels further. **Serum B-type natriuretic peptide,** a cardiac neurohormone released in response to increased ventricular wall tension, is elevated in adult patients with congestive heart failure. In children, B-type natriuretic peptide may be elevated in patients with heart failure as a result of systolic dysfunction (cardiomyopathy), as well as in children with volume overload (left-to-right shunts such as ventricular septal defect).

TREATMENT

The underlying cause of cardiac failure must be removed or alleviated if possible. If the cause is a congenital cardiac anomaly amenable to surgery, medical treatment of the heart failure is indicated to prepare the patient for surgery. With today's excellent outcomes of primary surgical repair of congenital heart defects, even in the neonatal period, few children require aggressive heart failure management to "grow big enough for surgery." In contrast, if the cause of heart failure is cardiomyopathy, medical management provides temporary relief from symptoms and may allow the patient to recover if the insult is reversible (e.g., myocarditis). If the lesion is not reversible, heart failure management usually allows the child to return to normal activities for some period and delay, sometimes for months or years, the need for heart transplantation.

General Measures

Strict bed rest is rarely necessary except in extreme cases, but it is important that the child be allowed to rest during the day as needed and sleep adequately at night. Some older patients feel better sleeping in a semi-upright position, using several pillows (orthopnea). For infants with heart failure, an infant chair may be advisable. After patients begin to respond to treatment, restrictions on activities can often be modified within the context of the specific diagnosis and the patient's ability. Formal cardiopulmonary exercise testing can be used to assess the patient's ability to perform exercise in a controlled environment and is useful for recommending rational exercise restrictions. For patients with pulmonary edema, positive pressure ventilation may be required along with other drug therapy. For those in low-output heart failure, positive pressure ventilation can significantly reduce total body oxygen consumption by eliminating the work of breathing, and help to reverse metabolic acidosis. β-Adrenergic agonists such as dopamine, dobutamine, and epinephrine are usually used in combination

with phosphodiesterase inhibitors such as milrinone. If the blood pressure will allow, afterload-reducing agents (nitroprusside, angiotensin-converting enzyme inhibitors [ACEIs] or angiotensin receptor blockers [ARBs]) may be beneficial. These agents are initiated in an intensive care setting with proper invasive monitoring of central venous and arterial blood pressure.

Diet

Infants with heart failure usually fail to thrive because of a combination of increased metabolic demands and decreased caloric intake. Increasing daily calories is an important aspect of their management. Increasing the number of calories per ounce of infant formula (or supplementing breastfeeding) may be beneficial. Many infants do not tolerate an increase beyond 24 calories/oz because of diarrhea or because these formulas provide too large a solute load for compromised kidneys.

Severely ill infants and children may lack sufficient strength for effective sucking because of extreme fatigue, rapid respirations, and generalized weakness. In these circumstances, nasogastric feedings may be helpful. In many patients with cardiac enlargement, gastroesophageal reflux is a major problem. The use of continuous drip nasogastric feedings at night, administered by pump, may improve caloric intake while decreasing problems with reflux. Occasionally, especially in infants with heart failure caused by complex congenital heart disease, medical or surgical intervention to correct reflux is necessary (Nissen fundoplication). Continued malnutrition may be an important factor in the decision to undertake earlier surgical intervention in patients who have an operable congenital heart lesion or for listing for transplantation in patients with cardiomyopathy.

The use of low-sodium formulas in the routine management of infants with heart failure is not recommended because these preparations are often poorly tolerated and may exacerbate diuretic-induced hyponatremia. Human breast milk is the ideal low-sodium nutritional source. The use of more potent diuretic agents allows more palatable standard formulas to be used for nutrition while controlling salt and water balance by chronic diuretic administration. Most older children can be managed with “no added salt” diets and abstinence from foods containing large amounts of sodium. A strict, extremely-low-sodium diet is rarely required, and rarely adhered to.

Diuretics

These agents interfere with reabsorption of water and sodium by the kidneys, which results in a reduction in circulating blood volume and thereby reduces pulmonary fluid overload and ventricular filling pressure. Diuretics are usually the first mode of therapy initiated in patients with congestive heart failure.

Furosemide is the most commonly used diuretic in pediatric patients with heart failure. It inhibits the reabsorption of sodium and chloride in the distal tubules and the loop of Henle. Patients requiring acute diuresis should be given intravenous or intramuscular furosemide at an initial dose of 1-2 mg/kg, which usually results in rapid diuresis and prompt improvement in clinical status, particularly if symptoms of pulmonary congestion are present. Chronic furosemide therapy is then prescribed at a dose of 1-4 mg/kg/24 hr given between 1 and 4 times a day. Careful monitoring of electrolytes is necessary with long-term furosemide therapy because of the potential for significant loss of potassium. Potassium chloride supplementation is usually required unless the potassium-sparing diuretic spironolactone is given concomitantly. Chronic administration of furosemide may cause contraction of the extracellular fluid compartment and result in “contraction alkalosis” (see Chapter 55.7). Diuretic-induced hyponatremia may become difficult to manage in patients with severe heart failure.

Spironolactone is an inhibitor of aldosterone and enhances potassium retention, often eliminating the need for oral potassium supplementation, which is frequently poorly tolerated. This drug is usually given orally in 2 divided doses of 2 mg/kg/24 hr. Combinations of spironolactone and chlorothiazide are sometimes used for convenience. Adults with heart failure have improved survival when an aldosterone inhibitor is included in the diuretic regimen.

Chlorothiazide is also used for diuresis in children with heart failure. It is less immediate in action and less potent than furosemide, and it affects the reabsorption of electrolytes in the renal tubules only. The usual dose is 10-40 mg/kg/24 hr in 2 divided doses. Potassium supplementation is often required if this agent is used alone.

Afterload Reducers, Including Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

These 2 groups of drugs reduce ventricular afterload by decreasing peripheral vascular resistance and thereby improving myocardial performance. Some of these agents also decrease systemic venous tone, which significantly reduces preload. Afterload reducers are especially useful in children with heart failure secondary to cardiomyopathy and in patients with severe mitral or aortic insufficiency. They may also be effective in patients with heart failure caused by left-to-right shunts. They are not generally used in the presence of stenotic lesions of the left ventricular outflow tract because of concern over coronary perfusion. ACEIs and ARBs may have additional beneficial effects on cardiac remodeling independent of their influence on afterload by directly influencing cardiac intracellular signaling pathways. In adult patients with dilated cardiomyopathy, the addition of an ACEI to standard medical therapy reduces both morbidity and mortality. Afterload-reducing agents are most often used in conjunction with other anticongestive drugs such as diuretics and, in some patients, digoxin.

Intravenously administered agents such as nitroprusside should be administered only in an intensive care setting and for as short a time as possible. Nitroprusside’s short intravenous half-life makes it ideal for titrating the dose in critically ill patients. Peripheral arterial vasodilation and afterload reduction are the major effects, but venodilation causing a decrease in venous return to the heart may also be beneficial. Blood pressure must be continuously monitored because sudden hypotension can occur. Consequently, nitroprusside is contraindicated in patients with preexisting hypotension. As the drug is metabolized, small amounts of circulating cyanide are produced and detoxified in the liver to thiocyanate, which is excreted in urine. When high doses of nitroprusside are administered for several days, toxic symptoms related to thiocyanate poisoning may occur (fatigue, nausea, disorientation, acidosis, and muscular spasm). If nitroprusside use is prolonged, blood thiocyanate levels should be monitored. Phosphodiesterase inhibitors (see later) are also excellent, although somewhat less-potent afterload-reducing agents, without the toxicity of nitroprusside.

The orally active ACEIs captopril and enalapril produce arterial dilation by blocking the production of angiotensin II, thereby resulting in significant afterload reduction. Venodilation and consequent preload reduction also have been reported. In addition, these agents interfere with aldosterone production and therefore also help control salt and water retention. ACEIs have additional beneficial effects on cardiac structure and function that may be independent of their effect on afterload. The oral dose for captopril is 0.3-6 mg/kg/24 hr given in 3 divided doses; for enalapril the oral dose is 0.05-0.5 mg/kg/24 hr given in 1 or 2 daily doses. Adverse reactions to ACEIs include hypotension and its sequelae (weakness, dizziness, syncope) and hyperkalemia. A maculopapular pruritic rash is encountered in a small number of patients, but the drug may be continued because the rash often disappears spontaneously with time. Neutropenia, renal toxicity, and chronic cough also occur.

Digitalis Glycosides

Digoxin, once the mainstay of heart failure management in both children and adults, is currently used less frequently, as a result of the introduction of newer therapies and the recognition of its potential toxicities. Many cardiologists will use digitalis as an adjunct to ACEIs and diuretics in patients with symptomatic heart failure, whereas others have moved away from its use altogether. Despite multiple clinical studies, predominantly in adults, the controversy over digitalis remains.

Digoxin is the digitalis glycoside used most often in pediatric patients. It has a half-life of 36 hr and it is absorbed well by the gastrointestinal tract (60-85%), even in infants. An initial effect can be seen as early as 30 min after administration, and the peak effect for oral digoxin occurs at ≈2-6 hr. When the drug is administered intravenously, the initial effect is seen in 15-30 min, and the peak effect occurs at 1-4 hr. The kidney eliminates digoxin, so dosing must be adjusted according to the patient's renal function. The half-life of digoxin may be up to 6 days in patients with anuria because slower hepatic excretion pathways are used in these patients.

Rapid digitalization of infants and children in heart failure may be carried out intravenously. The dose depends on the patient's age (Table 442-2). The recommended digitalization schedule is to give half the total digitalizing dose immediately and the succeeding 2 one-quarter doses at 12-hr intervals later. The electrocardiogram must be closely monitored and rhythm strips obtained before each of the 3 digitalizing doses. Digoxin should be discontinued if a new rhythm disturbance is noted. Prolongation of the P-R interval is not necessarily an indication to withhold digitalis, but a delay in administering the next dose or a reduction in the dosage should be considered, depending on the patient's clinical status. Minor ST segment or T-wave changes are commonly noted with digitalis administration and should not affect the digitalization regimen. Baseline serum electrolyte levels should be measured before and after digitalization. Hypokalemia and hypercalcemia exacerbate digitalis toxicity. Because hypokalemia is relatively common in patients receiving diuretics, potassium levels should be monitored closely in those receiving a potassium-wasting diuretic in combination with digitalis. In patients with active myocarditis, some cardiologists recommend avoiding digitalis altogether and if used, maintenance digitalis should be started at half the normal dose without digitalization due to the increased risk of arrhythmia in these patients.

Patients who are not critically ill may be given digitalis initially by the oral route, and in most instances digitalization is completed within 24 hr. When slow digitalization is desirable, for example, in the

Table 442-2 Dosage of Drugs Commonly Used for the Treatment of Congestive Heart Failure

DRUG	DOSAGE
DIGOXIN	
Digitalization (½ initially, followed by ¼ q12h × 2)	Premature: 20 μg/kg Full-term neonate (up to 1 mo): 20-30 μg/kg Infant or child: 25-40 μg/kg Adolescent or adult: 0.5-1 mg in divided doses NOTE: These doses are PO; IV dose is 75% of PO dose
Maintenance digoxin	5-10 μg/kg/day, divided q12h Trough serum level: 1.5-3.0 ng/mL <6 mo old; 1-2 ng/mL >6 mo old NOTE: These doses are PO; IV dose is 75% of PO dose
DIURETICS	
Furosemide (Lasix)	IV: 0.5-2 mg/kg/dose PO: 1-4 mg/kg/day, divided qd-qid
Bumetanide (Bumex)	IV: 0.01-0.1 mg/kg/dose PO: 0.01-0.1 mg/kg/day q24-48h
Chlorothiazide (Diuril)	PO: 20-40 mg/kg/day, divided bid or tid
Spironolactone (Aldactone)	PO: 1-3 mg/kg/day, divided bid or tid
Nesiritide (B-type natriuretic peptide)	IV: 0.001-0.03 μg/kg/min
ADRENERGIC AGONISTS (ALL IV)	
Dobutamine	2-20 μg/kg/min
Dopamine	2-30 μg/kg/min
Isoproterenol	0.01-0.5 μg/kg/min
Epinephrine	0.1-1.0 μg/kg/min
Norepinephrine	0.1-2.0 μg/kg/min
PHOSPHODIESTERASE INHIBITORS (ALL IV)	
Milrinone	0.25-1.0 μg/kg/min
AFTERLOAD-REDUCING AGENTS	
Captopril (Capoten), all PO	Prematures: start at 0.01 mg/kg/dose; 0.1-0.4 mg/kg/day, divided q6-24h Infants: 1.5-6 mg/kg/day, divided q6-12h Children: 2.5-6 mg/kg/day, divided q6-12h
Enalapril (Vasotec), all PO	0.08-0.5 mg/kg/day, divided q12-24h
Hydralazine (Apresoline)	IV: 0.1-0.5 mg/kg/dose (maximum: 20 mg) PO: 0.75-5 mg/kg/day, divided q6-12h
Nitroglycerin	IV: 0.25-0.5 μg/kg/min start; increase to 20 μg/kg/min maximum
Nitroprusside (Nipride)	IV: 0.5-8 μg/kg/min
β-ADRENERGIC BLOCKERS	
Carvedilol (Coreg)	PO: initial dose 0.1 mg/kg/day (maximum: 6.25 mg) divided bid, increase gradually (usually 2 wk intervals) to maximum of 0.5-1 mg/kg/day over 8-12 wk as tolerated; adult maximal dose: 50-100 mg/day
Metoprolol (Lopressor, Toprol-XL)	PO, nonextended release form: 0.2 mg/kg/day divided bid, increase gradually (usually 2 wk intervals) to maximum dose of 1-2 mg/kg/day PO, extended release form (Toprol-XL) is given once daily; adult initial dose 25 mg/day, maximum dose is 200 mg/day

Note: Pediatric doses based on weight should not exceed adult doses. Because recommendations may change, these doses should always be double-checked. Doses may also need to be modified in any patient with renal or hepatic dysfunction.

Maintenance digitalis therapy is started ≈12 hr after full digitalization. The daily dosage, one quarter of the total digitalizing dose, is divided in 2 and given at 12-hr intervals. The oral maintenance dose is usually 20-25% higher than when digoxin is used parenterally (see Table 442-2). The normal daily dose of digoxin for older children (>5 yr of age) calculated by body weight should not exceed the usual adult dose of 0.125-0.5 mg/24 hr.

immediate postoperative period, initiation of a maintenance digoxin schedule without a previous loading dose achieves full digitalization in 7-10 days.

Measurement of **serum digoxin levels** is useful under several circumstances: (1) when an unknown amount of digoxin has been administered or ingested accidentally, (2) when renal function is impaired or if drug interactions are possible, (3) when questions regarding compliance are raised, and (4) when a toxic response is suspected. Therapeutic trough blood levels are usually 2-4 ng/mL in infants and 1-2 ng/mL in older children. Exceeding these levels does not generally add significantly to the management of heart failure and only increases the risk of toxicity. In suspected toxicity, elevated serum digoxin levels are not in themselves diagnostic of toxicity but must be interpreted as an adjunct to other clinical and electrocardiographic findings (rhythm and conduction disturbances). Hypokalemia, hypomagnesemia, hypercalcemia, cardiac inflammation secondary to myocarditis, and prematurity may all potentiate digitalis toxicity. A cardiac arrhythmia that develops in a child who is taking digitalis may also be related to the primary cardiac disease rather than the drug, however, any arrhythmia occurring after the institution of digitalis therapy must be considered to be drug related until proven otherwise. There are many drugs that interact with digoxin and may increase levels or risk of toxicity, so care should be taken when a patient on digoxin is being considered for additional pharmacologic therapy of any kind.

α- and β-Adrenergic Agonists

These drugs are usually administered in an intensive care setting, where the dose can be carefully titrated to hemodynamic response. Continuous determinations of arterial blood pressure and heart rate are performed; measuring serial mixed venous oxygen saturations or cardiac output directly with a pulmonary thermodilution (Swan-Ganz) catheter may be helpful in assessing drug efficacy, although this technique is much less commonly used in children compared to adults. Though extremely efficacious in the acute intensive care setting, long-term administration of adrenergic agonists has been shown to increase morbidity and mortality in adults with heart failure and is usually avoided unless the patient is totally dependent on these agents.

Dopamine is a predominantly β-adrenergic receptor agonist, but it has α-adrenergic effects at higher doses. Dopamine has less chronotropic and arrhythmogenic effect than the pure β-agonist isoproterenol does. In addition, it results in selective renal vasodilation because of its interaction with renal dopamine receptors, which is particularly useful in patients with the compromised kidney function that is often associated with low cardiac output, although some recent studies in adults question the efficacy of dopamine for this indication. At a dose of 2-10 µg/kg/min, dopamine results in increased contractility with little peripheral vasoconstrictive effect. If the dose is increased beyond 15 µg/kg/min, however, its peripheral α-adrenergic effects may result in vasoconstriction. Fenoldopam is a dopamine DA1 receptor agonist and is used at a low dose (0.03 µg/kg/min) to increase renal blood flow and urine output. It can cause hypotension, so blood pressure should be carefully monitored.

Dobutamine, a derivative of dopamine, is also useful in treating low cardiac output. It has direct inotropic effects and causes a moderate reduction in peripheral vascular resistance. Dobutamine can be used alone or as an adjunct to dopamine therapy to avoid the vasoconstrictive effects of higher-dose dopamine. Dobutamine is also less likely to cause cardiac rhythm disturbances than isoproterenol is. The usual dose is 2-20 µg/kg/min.

Isoproterenol is a pure β-adrenergic agonist that has a marked chronotropic effect; it is most effective in patients with slow heart rates and is less commonly used in patients with heart failure and normal or increased heart rates, because of the increased risk of arrhythmias.

Epinephrine is a mixed α- and β-adrenergic receptor agonist that is usually reserved for patients with cardiogenic shock and low arterial blood pressure. Although epinephrine can raise blood pressure effectively, it also increases systemic vascular resistance, and therefore increases the afterload against which the heart has to work and is associated with an increased risk of arrhythmia.

Phosphodiesterase Inhibitors

Milrinone is useful in treating patients with low cardiac output who are refractory to standard therapy and has been shown to be highly effective in managing the low-output state present in children after open heart surgery. It works by inhibition of phosphodiesterase, which prevents the degradation of intracellular cyclic adenosine monophosphate. Milrinone has both positive inotropic effects on the heart and peripheral vasodilatory effects and has generally been used as an adjunct to dopamine or dobutamine therapy in the intensive care unit. It is given by intravenous infusion at 0.25-1 µg/kg/min, sometimes with an initial loading dose of 50 µg/kg. A major side effect is hypotension secondary to peripheral vasodilation, especially when a loading dose is used. The hypotension can generally be managed by the administration of intravenous fluids to restore adequate intravascular volume.

Chronic Treatment with β-Blockers

Studies in adults with dilated cardiomyopathy show that β-adrenergic blocking agents, introduced gradually as part of a comprehensive heart failure treatment program, improve exercise tolerance, decrease hospitalizations, and reduce overall mortality. The agents most often used are carvedilol, an agent with both α- and β-adrenergic receptor blocking as well as free radical scavenging effects and metoprolol, a β_1-adrenergic receptor selective antagonist. β-Blockers are used for the chronic treatment of patients with heart failure and should not be administered when patients are still in the acute phase of heart failure (i.e., receiving intravenous adrenergic agonist infusions). Although very efficacious in adults, clinical studies in children have shown mixed results, potentially due to the significant heterogeneity of the populations being studied and differences in the types of β-blocking agents.

ELECTROPHYSIOLOGIC APPROACHES TO HEART FAILURE MANAGEMENT

Significant improvements in symptomatology and functional capacity have been achieved in selected adult patients with cardiomyopathy using biventricular resynchronization pacing. This technique improves cardiac output by restoring normal synchrony between right and left ventricular contraction, which is often lost in patients with dilated cardiomyopathy (these patients usually manifest a left bundle branch block on electrocardiogram). There is growing experience with resynchronization pacing in children and reports show early success in patients with left ventricular failure (in the setting of cardiomyopathy), right ventricular failure (in the setting of previously repaired tetralogy of Fallot), and somewhat less so in patients with single ventricular failure (in the setting of complex congenital heart disease).

Arrhythmia is a leading cause of sudden death in patients with severe cardiomyopathy (both dilated and hypertrophic). Although antiarrhythmic medications can sometimes reduce this risk, for patients at particularly high risk (e.g., those with a condition known to be associated with a high risk of ventricular arrhythmia or those who have already experienced a "missed sudden death" episode), use of an implantable cardioverter-defibrillator can be lifesaving (see Chapter 429).

442.1 Cardiogenic Shock

Daniel Bernstein

Cardiogenic shock (see Chapter 70) may occur as a complication of (1) severe cardiac dysfunction before or after cardiac surgery, (2) septicemia, (3) severe burns, (4) anaphylaxis, (5) cardiomyopathy, (6) myocarditis, (7) myocardial infarction or stunning, and (8) acute central nervous system disorders. It is characterized by low cardiac output and hypotension, and therefore results in inadequate tissue perfusion.

Treatment is aimed at reinstitution of adequate cardiac output to prevent the untoward effects of prolonged ischemia on vital organs, as

Table 442-3	Treatment of Cardiogenic Shock*		
	DETERMINANTS OF STROKE VOLUME		
	Preload	**Contractility**	**Afterload**
Parameters measured	CVP, PCWP, LAP, cardiac chamber size on echocardiography	CO, BP, fractional shortening or ejection fraction on echocardiography, MV O_2 saturation	BP, peripheral perfusion, SVR
Treatment to improve cardiac output	Volume expansion (crystalloid, colloid, blood)	β-Adrenergic agonists, phosphodiesterase inhibitors	Afterload-reducing agents: milrinone, nitroprusside, ACE inhibitors

ACE, angiotensin-converting enzyme; BP, blood pressure; CO, cardiac output (measured with a thermodilation catheter); CVP, central venous pressure; LAP, left atrial pressure (measured with an indwelling LA line); MV O_2 saturation, mixed venous oxygen saturation (measured with a central venous catheter); PCWP, pulmonary capillary wedge pressure (measured with a thermodilation catheter); SVR, systemic vascular resistance (calculated from CO and mean BP).

*The goal is to improve peripheral perfusion by increasing cardiac output, where: cardiac output = heart rate × stroke volume.

well as management of the underlying cause. Under normal physiologic conditions, cardiac output is increased as a result of sympathetic stimulation, which increases both contractility and heart rate. If contractility is depressed, cardiac output can be improved by increasing heart rate, increasing ventricular filling pressure (preload) through the Frank-Starling mechanism, or by decreasing systemic vascular resistance (afterload). Optimal filling pressure is variable and depends on a number of extracardiac factors, including ventilatory support and intra-abdominal pressure. The increased pressure necessary to fill a relatively noncompliant ventricle should also be considered, particularly after open heart surgery, or in patients with restrictive or hypertrophic cardiomyopathies. If carefully administered incremental fluid does not result in improved cardiac output, abnormal myocardial contractility or an abnormally high afterload, or both, must be implicated as the cause of the low cardiac output. Although tachycardia is one mechanism to increase cardiac output, an excessive increase in heart rate may reduce cardiac output because of decreased time for diastolic filling.

Myocardial contractility usually improves when treatment of the basic cause of shock is instituted, hypoxia is eliminated, and acidosis is corrected. β-Adrenergic agonists such as dopamine, epinephrine, and dobutamine improve cardiac contractility, increase heart rate, and ultimately increase cardiac output. However, some of these agents also have α-adrenergic effects, which cause peripheral vasoconstriction and increase afterload, so careful consideration of the balance of these effects in an individual patient is important. The use of cardiac glycosides to treat acute low cardiac output states should be avoided.

Patients in cardiogenic shock may have a marked increase in systemic vascular resistance resulting in high afterload and poor peripheral perfusion. If the increased systemic vascular resistance is persistent and the administration of positive inotropic agents alone does not improve tissue perfusion, the use of afterload-reducing agents may be appropriate, for example, nitroprusside or milrinone in combination with a β-adrenergic agonist. Milrinone, which acts through inhibition of phosphodiesterase is also a positive inotropic agent, and combined with a β-adrenergic agonist, works synergistically to increase levels of myocardial cyclic adenosine monophosphate.

Sequential evaluation and management of cardiovascular shock are mandatory (see Chapter 70). Table 442-3 outlines the general treatment principles for acute cardiac circulatory failure under most circumstances. Treatment of infants and children with low cardiac output after cardiac surgery also depends on the nature of the operative procedure, any intraoperative complications, and the physiology of the circulation after repair or palliation (see Chapter 428). If cardiogenic shock does not respond rapidly to medical therapy, consideration of mechanical support is warranted. Modalities available for pediatric patients include extracorporeal membrane oxygenation for short-term support, and left and right ventricular assist devices for longer-term support.

Chapter 443

Pediatric Heart and Heart-Lung Transplantation

443.1 Pediatric Heart Transplantation

Daniel Bernstein

Pediatric heart transplantation is standard therapy for children with end-stage cardiomyopathy and other lesions not amenable to surgical repair. As of 2010, >7,500 heart transplants had been performed on children in the United States and Europe, with ≈500 transplants annually; a quarter of these being performed on children <1 yr of age. Survival rates among children compare favorably with those of adults. For children transplanted in the 1980s and early 1990s, 1 yr survival has been 75-80%, whereas for those transplanted after 2000, 1 yr survival is now in the range of 90%; during the same time periods, 5 yr survival has improved from 60-65% to 75% (Fig. 443-1). A growing number of children are now reaching their 15, 20, and 30 yr posttransplant anniversaries.

INDICATIONS

Heart transplantation is performed in infants and children with end-stage cardiomyopathy who have become refractory to medical therapy, in patients with previously repaired or palliated congenital heart disease who have developed ventricular dysfunction or other nonoperable late-term complications, and (less frequently) in patients with complex congenital heart disease (pulmonary atresia with intact septum and coronary arterial stenoses, some forms of hypoplastic left-heart syndrome) for whom standard surgical procedures are extremely high risk. Cardiomyopathies account for >50% of heart transplants in pediatric patients older than 1 yr, with the percentage of patients with previously repaired complex congenital heart lesions at ~30%. In infants younger than 1 yr, congenital heart lesions used to represent >80% of transplants; this fraction has dropped to ~60% as standard surgical results for complex congenital heart disease (hypoplastic left heart syndrome) have improved.

RECIPIENT AND DONOR SELECTION

Potential heart transplant recipients must be free of serious noncardiac medical problems such as neurologic disease, active systemic infection, severe hepatic or renal disease, and severe malnutrition. Many children with ventricular dysfunction are at risk for the development of pulmonary vascular disease, which if severe enough would preclude heart transplantation. Therefore, pulmonary vascular resistance is measured

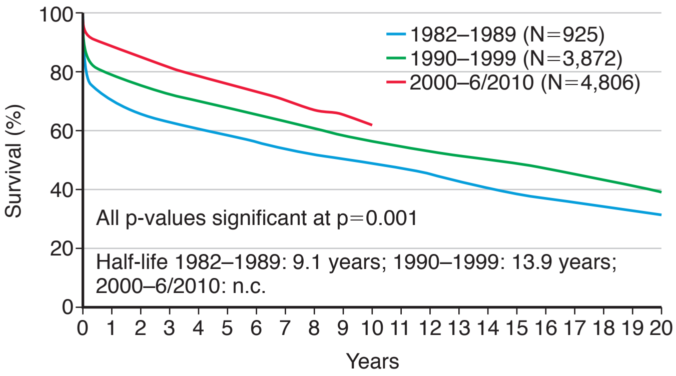

Figure 443-1 Survival after pediatric heart transplantation comparing current and past eras, based on >9,600 patients who received heart transplants in the United States and Europe from 1982 through 2010, as listed with the Registry of the International Society for Heart and Lung Transplantation. Survival has significantly improved over each successive time period. *(From Kirk R, Edwards LB, Kucheryavaya AY, et al. The Registry of the International Society for Heart and Lung Transplantation: thirteenth official pediatric heart transplantation report—2010.* J Heart Lung Transplant *29:1119–1128, 2010, Fig. 7.)*

at cardiac catheterization in heart transplant candidates, both at rest and, if elevated, in response to vasodilators. Patients with fixed elevated pulmonary vascular resistance are at higher risk for heart transplantation and may be considered candidates for either heterotopic heart transplantation (see later) or heart-lung transplantation (see Chapter 443.2). However, with recent advances in postoperative management of pulmonary hypertension (e.g., inhaled nitric oxide), many patients with moderate elevations in pulmonary vascular resistance can undergo heart transplant alone. A comprehensive social services evaluation is an important component of the recipient evaluation. Because of the complex posttransplantation medical regimen, the family must have a history of compliance. Detailed informed consent indicating that the family (and if old enough, the patient) understand the lifelong commitment to immunosuppressive medication and careful monitoring, must be obtained.

Donor shortage is a serious problem for both adults and children. At the national registry of transplant recipients in the United States (the United Network for Organ Sharing [UNOS]), allografts are matched by ABO blood group and body weight. HLA matching is not currently performed unless the recipient has preformed antibodies against a particular HLA antigen, in which case a prospective crossmatch can be obtained. ABO matching may not be required for young infants; the exact age under which ABO tolerance develops has not yet been determined. Contraindications to organ donation include prolonged cardiac arrest with persistent moderate to severe cardiac dysfunction, ongoing systemic illness or infection, and preexisting severe cardiac disease. Physicians caring for a patient who may be a potential donor should always contact the organ donor coordinator at their institution, who can best judge the appropriateness of organ donation and has experience in interacting with potential donor families. A history of resuscitation alone or reparable congenital heart disease is not an automatic exclusion for donation.

The decision of when to place a patient on the transplant waiting list is based on a combination of many factors, including poor ventricular function, markedly decreased exercise tolerance as determined by cardiopulmonary exercise testing (see Chapter 423.5), poor response to medical anticongestive therapy, multiple hospitalizations for heart failure, arrhythmia, progressive deterioration in renal or hepatic function, early stages of pulmonary vascular disease, and poor nutritional status. In patients awaiting transplantation, those with poor left ventricular function are usually started on a regimen of anticoagulation to reduce the risk of mural thrombosis and thromboembolism. Patients with low cardiac output resulting in decreases in end-organ (renal or hepatic) function unresponsive to standard pharmacologic treatment, or those that require chronic assisted ventilation or high-dose inotropic agents are now considered candidates for placement of left ventricular or biventricular assist devices, which can stabilize hemodynamics, improve renal and hepatic function, allow for extubation, and serve as a bridge to transplantation (see Chapter 442). The more recent availability of ventricular assist devices (e.g., the Berlin Heart EXCOR) that are small enough to support young infants has revolutionized the approach to supporting pediatric patients awaiting cardiac transplantation. The role of extracorporeal membrane oxygenation (ECMO) for these patients has been reduced; the need for ECMO support is still a risk factor for poorer outcomes after transplant. There is now limited but growing experience with totally implantable artificial heart devices in older children and adolescents, used either as a bridge to transplant, or in cases (e.g., children with peripheral muscular disorders) where transplantation would be a much higher risk.

PERIOPERATIVE MANAGEMENT

In the classic operation, both donor and recipient hearts were excised so that the posterior portions of the atria containing the venae cavae and pulmonary veins are left intact. The aorta and pulmonary artery are divided above the level of the semilunar valves. The anterior portion of the donor's atria was then connected to the remaining posterior portion of the recipient's atria, thereby avoiding the need for delicate suturing of the venae cavae or pulmonary veins. The donor and recipient great vessels were connected via end-to-end anastomoses. This has largely been supplanted by the bicaval anastomosis, with the donor right atrium (and sinus node) left intact and the suture lines at the superior and inferior vena cavae; the left atrial connection is still performed as in the classic procedure. **Heterotopic heart transplantation** has been used occasionally for patients with left ventricular cardiomyopathy and elevated pulmonary vascular resistance. In this operation, the donor and recipient hearts are connected in parallel so that the recipient right ventricle (which has hypertrophied over time as a result of the elevated pulmonary pressures) pumps mostly to the lungs, and the donor left ventricle pumps mostly to the body. This operation may be preferable to heart-lung transplant for appropriate candidates (patients with pulmonary hypertension but without parenchymal lung disease, without evidence of right ventricular failure, and without serious congenital heart disease), as it is associated with a greater survival at all posttransplant time points.

In the immediate postoperative period, **immunosuppression** is achieved with either a triple- or double-drug regimen, with more centers adopting a minimal steroid or steroid-free regimen. The most common combinations are a calcineurin inhibitor (either cyclosporine or tacrolimus) plus a white blood cell enzyme inhibitor (mycophenolate mofetil or azathioprine), plus or minus prednisone. In many centers, induction therapy (usually an antilymphocyte preparation) is added in the 1st wk, either antithymocyte globulin (ATG) or the humanized anti–interleukin 2 receptor antibodies (basiliximab). In children who do not experience significant graft rejection, steroids can be gradually eliminated after the 1st 6-12 mo. Some centers do not use steroids as part of maintenance immunosuppression, but do use them as bolus treatment for acute rejection episodes.

Most pediatric heart transplant recipients can be extubated within the 1st 48 hr after transplantation and are out of bed within 3-4 days. These patients are often discharged within the 1st 2 wk after transplantation. In patients with preexisting high-risk factors, postoperative recovery may be considerably prolonged. For those with preoperative pulmonary hypertension, the use of nitric oxide in the postoperative period can buy time to allow the donor right ventricle to hypertrophy in response to elevated pulmonary artery pressures. Occasionally, these patients will require right ventricular assist device support.

DIAGNOSIS AND MANAGEMENT OF ACUTE GRAFT REJECTION

Posttransplantation management consists of adjusting medications to maintain a balance between the risk of rejection and the side effects of over-immunosuppression. Along with infection, acute graft rejection is a leading cause of death in pediatric heart transplant

recipients. The incidence of acute rejection is greatest in the 1st 3 mo after transplantation and decreases considerably thereafter. Many pediatric patients experience at least 1 episode of acute rejection in the 1st 2 yr after transplantation, although modern immunosuppressive regimens have decreased the frequency of serious rejection episodes. Because the symptoms of rejection can mimic many routine pediatric illnesses (pneumonia, gastroenteritis), *it is mandatory that the transplant center be notified whenever a heart transplant recipient is seen in the pediatrician's office or emergency room for any acute illness*.

Clinical manifestations of **acute rejection** may include fatigue, fluid retention, fever, diaphoresis, abdominal symptoms, and a gallop rhythm. The electrocardiogram may show reduced voltage, atrial or ventricular arrhythmias, or heart block but is usually nondiagnostic. Roentgenographic examination may show an enlarged heart, effusions, or pulmonary edema, but usually only in the more advanced stages of rejection. Most rejection episodes occur without any detectable clinical symptoms. On echocardiography, indices of systolic left ventricular function may be decreased; however, these usually do not deteriorate until rejection is at least moderately severe. Techniques to evaluate wall thickening and left ventricular diastolic function have not fulfilled their promise as predictors of early rejection. Most transplant centers do not rely on echocardiography alone for rejection surveillance.

Myocardial biopsy is the most reliable method of monitoring patients for rejection. Biopsy specimens are taken from the right ventricular side of the interventricular septum and can be harvested relatively safely, even in small infants. In older children, myocardial biopsies may be performed as often as every 1-4 wk during the 1st 3-6 mo after transplantation. The frequency is then reduced over the next 2 yr to between 2 and 4 biopsies per year unless the patient has an episode of rejection. In infants, surveillance biopsies are usually performed less often and may be as infrequent as once or twice per year. Children may have clinically unsuspected rejection episodes even 5-10 yr after transplantation; most pediatric transplant centers continue routine surveillance biopsies, albeit at less-frequent intervals (every 6-12 mo).

Criteria for **grading cardiac rejection** are based on a system developed by the International Society for Heart and Lung Transplantation (ISHLT); these criteria take into account the degree of cellular infiltration and whether myocyte necrosis is present. ISHLT rejection grade 1R (former grades 1A, 1B, and 2) is usually mild enough that it is often not treated with bolus steroids, and many of these episodes resolve spontaneously. A repeat biopsy specimen is often obtained within a shorter time frame. For patients with ISHLT grade 2R (formerly grade 3A) rejection, treatment is instituted with either intravenous methylprednisolone or a "bump and taper" of oral prednisone. Asymptomatic patients >3 mo posttransplant and with normal echocardiograms are often treated as outpatients. Patients with grade 3R (formerly grades 3B or 4), or anyone with hemodynamic instability, are admitted to the hospital for intravenous steroid and potentially more aggressive antirejection therapy. For rejection episodes resistant to steroid therapy, additional therapeutic regimens include a repeat course of an antilymphocyte preparation (antithymocyte globulin), methotrexate, or total lymphoid irradiation. Patients with repeated episodes of rejection may also benefit from being switched from cyclosporine to tacrolimus (or vice versa). Refractory rejection is not considered a good indication for retransplantation because of the relatively poor outcomes compared with other indications for retransplantation.

Gene expression profiling of peripheral blood mononuclear cells has been validated in adults as a highly sensitive, and moderately selective, method of rejection surveillance. These results have not been confirmed in children. Other current techniques which may hold promise include the profiling of donor cell free DNA released in the serum of patients during episodes of graft injury. Progress has also been made in genetic profiling as a means to determine which patients are most at risk for rejection. Children who have single-nucleotide polymorphisms leading to greater activity of inflammatory cytokines or decreased activity of regulatory cytokines are at increased risk of rejection. This type of profiling may be useful in designing patient-specific immunosuppressive regimens in the future.

Some rejection episodes are not associated with a cellular infiltrate on biopsy. These cases of acellular or humoral rejection are mediated by circulating antibodies and can be detected by immunostaining of the biopsy specimen for the complement component C4d, for macrophages expressing CD68, and for evidence of histologic damage. Humoral rejection is less responsive to standard therapies for acute cellular rejection (e.g., bolus steroids) and has been treated with plasmapheresis, intravenous immunoglobulin, the anti-CD20 monoclonal antibody rituximab, and the proteasome inhibitor bortezomib, all with mixed results.

COMPLICATIONS OF IMMUNOSUPPRESSION

Infection

Infection is 1 of the 2 leading causes of death in pediatric transplant patients (Fig. 443-2). The incidence of infection is greatest in the 1st 3 mo after transplantation when immunosuppressive doses are highest. Viral infections are the most common, which accounts for as many as 25% of infectious episodes. Cytomegalovirus (CMV) infection used to be 1 of the leading causes of morbidity and mortality and may occur as a primary infection in patients without previous exposure to the virus or as a reactivation. Severe CMV infection can be disseminated or associated with pneumonitis or gastroenteritis and may provoke an episode of acute graft rejection or graft coronary disease. Most centers use intravenous ganciclovir or CMV immune globulin (CytoGam), or both, as prophylaxis in any patient receiving a heart from a donor who is positive for CMV or in any recipient who has serologic evidence of previous CMV disease. Oral preparations of ganciclovir with improved absorption profiles are available for chronic therapy and have largely replaced intravenous preparations for prophylaxis. These regimens have significantly reduced the burden of CMV disease in heart transplant patients. Polymerase chain reaction enhances the ability to diagnose CMV infection and to monitor the efficacy of therapy serially.

Most normal childhood viral illnesses are well tolerated and do not usually require special treatment. Otitis media and routine upper respiratory tract infections can be treated in the outpatient setting, although fever or symptoms that last beyond the usual course require further investigation. Gastroenteritis, especially with vomiting, can result in markedly reduced absorption of immunosuppressive medications and provoke a rejection episode. In this setting, drug levels should be closely monitored and the use of intravenous medications considered. Gastroenteritis can also be a sign of rejection, so a high index of suspicion must always be maintained. Varicella is another childhood illness of some concern for immunosuppressed patients. If a heart transplant recipient acquires clinical varicella infection, treatment with intravenous acyclovir usually attenuates the illness.

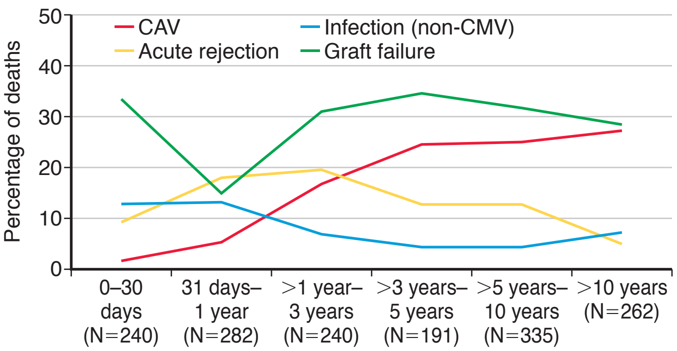

Figure 443-2 **Major causes of death after pediatric heart transplantation by time since transplant.** CAV, coronary artery vasculopathy; CMV, cytomegalovirus. *(From Kirk R, Edwards LB, Kucheryavaya AY, et al. The Registry of the International Society for Heart and Lung Transplantation: thirteenth official pediatric heart transplantation report—2010.* J Heart Lung Transplant *29:1119–1128, 2010, Fig. 9.)*

Bacterial infections are the next most frequent, with the lung being the most common site of infection (35%), followed by the blood, the urinary tract, and, less commonly, the sternotomy site. Other sources of posttransplantation infection include fungi (14%) and protozoa (6%). Many centers use nystatin mouthwash to decrease fungal colonization and trimethoprim/sulfamethoxazole (Bactrim, Septra) during the time a patient is on steroids as prophylaxis to prevent *Pneumocystis carinii* infection.

Growth Retardation

Patients requiring chronic steroid administration usually have decreased linear growth, thus most pediatric transplant programs aim for steroid-free immunosuppression within the 1st yr posttransplant. In those patients who experience rejection when steroids are withdrawn, alternate-day steroid regimens result in improved linear growth. Total lymphoid irradiation has shown promise as a steroid-sparing protocol. Despite these concerns, 75% of long-term survivors of pediatric heart transplantation have normal growth.

Hypertension

Hypertension is common in patients treated with cyclosporine, caused by a combination of plasma volume expansion and defective renal sodium excretion. Corticosteroids usually potentiate cyclosporine-induced hypertension. Patients are typically managed with a combination of a diuretic and a vasodilator. Agents that work via calcium channel blockade have the additional advantage of possibly attenuating graft coronary disease. The incidence of hypertension is slightly lower in patients treated with tacrolimus.

Renal Function

Chronic administration of cyclosporine or tacrolimus can lead to a tubulointerstitial nephropathy in adults, but severe renal dysfunction is less common in children. Most pediatric patients gradually have an increase in serum creatinine in the 1st yr after transplantation; if renal dysfunction occurs, it usually responds to a decrease in calcineurin inhibitor dosage. The addition of sirolimus, a target of rapamycin inhibitor, instead of mycophenolate allows a reduction in the dose of calcineurin inhibitor in patients with renal dysfunction. Infection with BK virus, a growing problem in renal transplant patients, has been described as a source of renal dysfunction in heart transplant patients. Fortunately, pediatric heart transplant patients infrequently require renal transplantation long-term.

Neurologic Complications

Neurologic side effects of cyclosporine and tacrolimus include tremor, myalgias, paresthesias, and, rarely, seizures. These complications can be treated with reduced doses of medication and occasionally with oral magnesium supplementation. Intracranial infections pose a significant risk, especially because some of the more frequent signs (nuchal rigidity) may be absent in immunosuppressed patients. Potential organisms include *Aspergillus, Cryptococcus neoformans,* and *Listeria monocytogenes.* A rare form of encephalopathy, known as PRES (posterior reversible encephalopathy syndrome) can occur in patients on calcineurin inhibitors (either cyclosporine or tacrolimus). PRES presents with hypertension, headaches and seizures, requires MRI for diagnosis, and is usually managed by changing calcineurin inhibitor or in rare cases eliminating calcineurin inhibitors totally in favor of other immunosuppressive agents (e.g., sirolimus/mycophenolate).

Tumors

One of the serious complications limiting long-term survival in pediatric heart transplant patients is the risk of neoplastic disease. The most common is posttransplant lymphoproliferative disease (PTLD), a condition associated with Epstein-Barr virus infection. Patients who are Epstein-Barr virus seronegative at the time of transplant (usually infants and young children) are at increased risk of developing PTLD if they subsequently seroconvert, acquiring the virus either from the donor organ or from primary infection (mononucleosis). Unlike true cancer, many cases of PTLD respond to a reduction in immunosuppression plus antiviral therapy with acyclovir. A monoclonal antibody directed against the CD20 antigen on activated lymphocytes (rituximab) has been effective against some forms of PTLD. However, PTLD can behave more aggressively and many cases eventually require chemotherapy. An increased risk of skin cancer requires that children use appropriate precautions when exposed to sunlight.

Chronic Rejection

Graft coronary artery disease (GCAD) is a manifestation of chronic graft rejection that occurs in ≈20% of children 5 yr after transplant. The cause is still unclear, although it is thought to be a form of immunologically mediated vessel injury (chronic rejection). Hypercholesterolemia and hyperglycemia are thought to increase the risk of this disease. Unlike native coronary atherosclerosis, GCAD is a diffuse process with a high degree of distal vessel involvement. Because the transplanted heart has been denervated, patients may not experience symptoms such as angina pectoris during ischemic episodes, and the initial manifestation may be cardiovascular collapse or sudden death. Most centers perform coronary angiography annually to screen for coronary abnormalities; some also perform coronary intravascular ultrasound on adolescents. Standard coronary artery bypass procedures are usually not helpful because of the diffuse nature of the process, although transcatheter stenting can sometimes be effective for isolated lesions. For severe cases, repeat heart transplantation has been the only effective treatment. Thus, prevention has been the focus of most current research. The cell-cycle inhibitors sirolimus and everolimus have been shown to decrease coronary arterial intimal thickening in adult transplant patients. Other drugs that have been shown to reduce the risk of GCAD include the calcium channel blockers (such as diltiazem) and the cholesterol-lowering HMG-CoA (3-hydroxy-3-methyl-coenzyme A) reductase inhibitors (such as pravastatin or atorvastatin).

Other Complications

Corticosteroids usually result in cushingoid facies, steroid acne, and striae. Cyclosporine can cause a subtle change in facial features such as hypertrichosis and gingival hyperplasia. These cosmetic features can be particularly disturbing to adolescents and may be the motivation for noncompliance, one of the leading risks for late morbidity and mortality. Most of these cosmetic complications are dose related and improve as immunosuppressive medications are weaned. Osteoporosis and aseptic necrosis are additional reasons for reducing the steroid dosage as soon as possible. Diabetes and pancreatitis are rare but serious complications.

Rehabilitation

Despite the potential risks of immunosuppression, the prospect for rehabilitation in pediatric heart transplant recipients is excellent. More than 95% of pediatric heart transplant recipients have no functional limitations in their daily lives. The majority of patients do not require rehospitalization for transplant-related problems.

Pediatric heart transplant recipients can attend daycare or school and participate in non-collision competitive sports (no tackle football or martial arts) and other age-appropriate activities. Standardized measurements of ventricular function are close to normal. Because the transplanted heart is denervated, the increase in heart rate and cardiac output during exercise is slower in transplant recipients, and maximal heart rate and cardiac output responses are mildly attenuated. These subtle abnormalities are rarely noticeable by the patient.

Growth of the transplanted heart is excellent, although a mild degree of ventricular hypertrophy is commonly seen, even years after transplantation. The sites of atrial and great vessel anastomoses usually grow without the development of obstruction. In neonates who undergo transplantation for hypoplastic left heart syndrome, however, juxtaductal aortic coarctation may recur.

As assessed by standardized testing, the psychologic adjustment to heart transplantation in children is usually good. However, a serious problem with noncompliance often occurs once patients reach

adolescence, and life-threatening rejection may result. Early intervention by social workers, counselors, and psychologists may be able to reduce this risk.

Bibliography is available at Expert Consult.

443.2 Heart-Lung and Lung Transplantation

Daniel Bernstein

More than 670 heart-lung and 1,700 lung (single or double) transplants have been performed in children in the United States and Europe, with ≈140 procedures performed annually. Primary indications for heart-lung transplantation include cystic fibrosis, primary pulmonary hypertension, complex congenital heart disease with pulmonary hypoplasia or Eisenmenger syndrome, congenital lung abnormalities, and end-stage parenchymal lung disease (bronchopulmonary dysplasia, chronic lung disease, and interstitial fibrosis). Many of these patients with normal hearts are candidates for single- or double-lung transplantation if right ventricular function is preserved and there has been a trend towards decreasing combined heart-lung transplant for this reason. In some patients with Eisenmenger physiology, double-lung transplantation can be performed in combination with repair of intracardiac defects. Patients with cystic fibrosis are not candidates for single-lung grafts because of the risk of infection from the diseased contralateral lung. Patients are selected according to many of the same criteria as for heart transplant recipients (see Chapter 443.1).

Posttransplant immunosuppression is usually achieved with a triple-drug regimen, combining a calcineurin inhibitor (cyclosporine or tacrolimus) with a white blood cell enzyme inhibitor (mycophenolate or azathioprine) and prednisone. Most patients receive induction therapy with an antithymocyte or anti-T cell preparation. Unlike patients with isolated heart transplants, patients with heart or heart-lung transplants cannot be weaned totally off steroids. Prophylaxis against *P. carinii* infection is achieved with trimethoprim-sulfamethoxazole or aerosolized pentamidine. Ganciclovir and CMV immune globulin prophylaxis are used as in heart transplant recipients (see Chapter 443.1).

Pulmonary rejection is common in lung or heart-lung transplant recipients, whereas heart rejection is encountered much less often than in patients with isolated heart transplants. Symptoms of lung rejection may include fever and fatigue, although many episodes are minimally symptomatic. Surveillance for rejection is performed by monitoring pulmonary function (forced vital capacity; forced expiratory volume in 1 sec [FEV_1]; forced expiratory flow, midexpiratory phase [$FEF_{25-75\%}$]), systemic arterial oxygen tension, and chest roentgenograms and by transbronchial biopsy.

Actuarial survival rates after lung or heart-lung or lung transplantation in children are currently 75% at 1 yr and 50% at 5 yr; improved patient selection and postoperative management are continually improving these survival statistics from prior eras. Graft failure and infection are the leading cause of early death, whereas a form of chronic rejection known as **bronchiolitis obliterans** accounts for nearly 50% of late mortality. Other causes of early morbidity and mortality include tracheal complications, pulmonary venous obstruction, donor lung dysfunction, bleeding, and acute rejection. Additional late complications include the development of airway stenosis, late graft failure, PTLD, and other side effects of chronic immunosuppression.

Postoperative indices of cardiopulmonary function and exercise capacity show significant improvement. Nearly 90% of patients are without activity limitations at 3 yr follow-up and more than 80% at 5 yr follow-up. Problems of donor availability are even more severe with lung transplantation than with isolated heart transplantation. Living related lung transplantation, in which a lobe from a parent is transplanted into a child, has been used to partially alleviate this problem.

Section 8

Diseases of the Peripheral Vascular System

Chapter 444

Diseases of the Blood Vessels (Aneurysms and Fistulas)

444.1 Kawasaki Disease

Daniel Bernstein

See also Chapter 166.

Aneurysms of the coronary and occasionally the systemic arteries may complicate Kawasaki disease and are the leading cause of morbidity in this disease (Figs. 444-1 and 444-2). Other than in Kawasaki disease, aneurysms are not common in children and occur most frequently in the aorta in association with coarctation of the aorta, patent ductus arteriosus, Ehlers-Danlos type IV (arterial ecchymotic form), hyperimmunoglobulin E syndrome, and Marfan syndrome and in intracranial vessels (see Chapter 601). They may also occur secondary to an infected embolus; infection contiguous to a blood vessel; trauma; congenital abnormalities of vessel structure, especially the medial wall; and arteritis, for example, polyarteritis nodosa, Behçet syndrome, and Takayasu arteritis (see Chapter 167.2).

444.2 Arteriovenous Fistulas

Daniel Bernstein

Arteriovenous fistulas may be limited and small or may be extensive producing systemic complications (see Chapters 505 and 650). The most common sites in infants and children are within the cranium, in the liver, in the lung, in the extremities, and in vessels in or near the thoracic wall. These fistulas, though usually congenital, may follow trauma or be a manifestation of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease). Femoral arteriovenous fistulas are a rare complication of percutaneous femoral catheterization.

CLINICAL MANIFESTATIONS

Clinical symptoms occur only in association with large arteriovenous communications when arterial blood flows into a low-pressure venous system without the resistance of the capillary bed; local venous pressure is increased, and arterial flow distal to the fistula is decreased. Systemic arterial resistance falls because of the runoff of blood through the fistula. Compensatory mechanisms include tachycardia and increased stroke volume so that cardiac output rises. Total blood volume is also increased. In large fistulas, left ventricular dilation, a widened pulse pressure, and high output heart failure occur. CT, MRI, or injection of contrast material into an artery proximal to the fistula confirms the diagnosis.

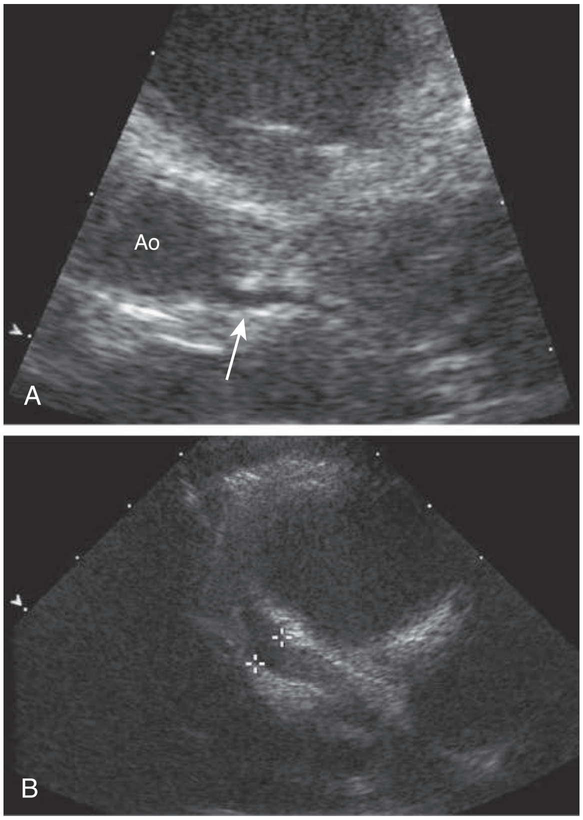

Figure 444-1 Two-dimensional echocardiogram comparing a normal left main coronary artery (*arrow* in **A**) with a giant coronary artery aneurysm (outlined by *cross marks* in **B**) in a patient with Kawasaki disease. Ao, aorta.

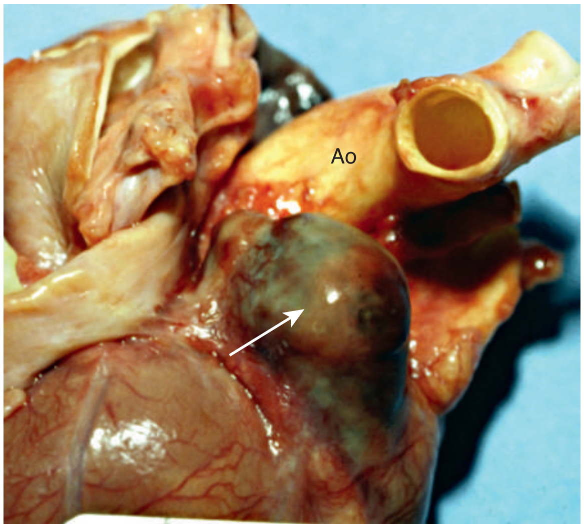

Figure 444-2 Pathologic specimen showing giant aneurysm of left main coronary artery *(arrow).* Ao, ascending aorta.

Large intracranial arteriovenous fistulas most often occur in newborn infants in association with a **vein of Galen malformation.** The large intracranial left-to-right shunt results in heart failure secondary to the demand for high cardiac output. Patients with smaller communications may not have cardiovascular manifestations but may later be disposed to hydrocephalus (see Chapter 591.11) or seizure disorders. The diagnosis can often be made by auscultation of a continuous murmur over the cranium. Older children with more diffuse intracranial arteriovenous malformations may be recognized on the basis of intracranial calcification and high cardiac output without cardiac failure.

Hepatic arteriovenous fistulas may be generalized or localized in the liver and may be hemangioendotheliomas or cavernous hemangiomas. The fistula may be located between the hepatic artery and the ductus venosus or portal vein. Congenital hemorrhagic telangiectasia may also be present. Large arteriovenous fistulas are associated with increased cardiac output and heart failure. Hepatomegaly is usual, and systolic or continuous murmurs may be audible over the liver.

Peripheral arteriovenous fistulas generally involve the extremities and are associated with disfigurement, swelling of the extremity, and visible hemangiomas. Some are located in areas that result in upper airway obstruction. Because only a small minority results in large arterial runoff, cardiac failure is uncommon.

TREATMENT

Medical management of heart failure is initially helpful in neonates with these conditions; with time, the size of the shunt may diminish and symptoms spontaneously regress. Hemangiomas of the liver often eventually disappear completely. Large liver hemangiomas have been treated with steroids, ε-aminocaproic acid, interferon, local compression, embolization, or local irradiation; the beneficial effects of these management options are not firmly established because individual patients display marked variation in clinical course without treatment. Catheter embolization is becoming the treatment of choice for many patients with a symptomatic arteriovenous fistula. Embolic agents that have been used include detachable balloons, steel (Gianturco) coils, and liquid tissue adhesives (cyanoacrylate). Often, multiple procedures are necessary before flow is significantly reduced. Gamma knife radiosurgery has been used successfully in patients with cerebral arteriovenous malformations. Surgical removal of a large fistula may be attempted in patients with severe cardiac failure and lack of improvement with medical treatment. Surgical treatment may be contraindicated or unsuccessful when the lesion is extensive and diffuse or is located in a position where adjoining tissue may be injured during the surgery or related procedures.

444.3 Generalized Arterial Calcification of Infancy/Idiopathic Infantile Arterial Calcification

Robert M. Kliegman

Generalized arterial calcification of infancy (GACI) is a rare and often lethal autosomal recessive disorder characterized by calcification of muscular arteries with fibrotic myointimal proliferation and subsequent vascular stenosis leading to tissue ischemia, poor function or infarction. Diffuse arterial calcification may begin in utero leading to hydrops fetalis; in the neonate diffuse arterial calcification leads to respiratory distress and heart failure or myocardial infarction (coronary, pulmonary arteries), hypertension (renal arteries), and poor femoral pulses (aorta, femoral arteries).

Mutations in the ectonucleotide pyrophosphatase 1gene (*ENPP1*) are noted in 75% of patients. Serum calcium, phosphate and alkaline phosphatase levels are normal and although the vascular calcification may be seen on plain x-rays (Fig. 444-3), ultrasonography (Fig. 444-4), or CT scans may reveal calcifications not visible on plain films.

A subset of patients with GACI have monoallelic or biallelic mutations in the adenosine triphosphate–binding cassette subfamily C number 6 gene (*ABCC6*), which is the gene responsible for pseudoxanthoma elasticum (PXE). PXE, an autosomal recessive disorder, is classically associated with a later onset of ectopic mineralization of elastic fibers in the skin, eyes and arteries. In addition, some surviving infants with *ENPP1* mutation develop PXE symptoms involving skin and retina (angioid streaking).

Infants with GACI have been treated with bisphosphonates with variable success. In addition, some survivors have developed hypophosphatemic rickets.

444.4 Arterial Calcifications Caused by Deficiency of CD73

Robert M. Kliegman

This rare autosomal recessive disorder, due to mutations in the 5 exonucleotidase CD73 (*NT5E*) results in joint and arterial (lower extremity) calcification in adults. Patients present with intermittent claudication and joint pain. Onset is probably before adulthood, as patients may be undiagnosed with nonspecific findings during adolescence.

Chapter 445

Systemic Hypertension

Marc B. Lande

Primary (essential) hypertension occurs commonly in adults and, if untreated, is a major risk factor for myocardial infarction, stroke, and renal failure. In adults with hypertension, a 5 mm Hg increase in diastolic blood pressure (BP) increased the risk of coronary artery disease by 20% and the risk of stroke by 35%. Furthermore, hypertension is implicated in the etiology of nearly 50% of adults with end-stage renal disease. The prevalence of adult hypertension increases with age, ranging from 15% in young adults to 60% in individuals older than 65 yr.

Hypertensive children, although usually asymptomatic, already manifest evidence of target organ damage. Up to 40% of hypertensive children have left ventricular hypertrophy and hypertensive children have increased carotid intima–media thickness, a marker of early atherosclerosis. Primary hypertension during childhood often tracks into adulthood. Children with BP >90th percentile have a 2.4-fold greater risk of having hypertension as adults. Similarly, nearly half of hypertensive adults had a BP >90th percentile as children. There is also an association between childhood hypertension and early atherosclerosis in young adulthood.

PREVALENCE OF HYPERTENSION IN CHILDREN

In infants and young children, systemic hypertension is uncommon, with a prevalence of <1%, but when present, it is often indicative of an underlying disease process **(secondary hypertension)**. *Severe and symptomatic hypertension in children is usually caused by secondary hypertension.* In contrast, the prevalence of primary essential hypertension, mostly in older school-age children and adolescents, has increased in prevalence in parallel with the obesity epidemic. School screening studies show that approximately 10% of U.S. youth overall have prehypertension and 2.5% have hypertension. The influence of obesity on elevated BP is evident in children as young as 2-5 yr old. Approximately 20% of American youth are obese, and up to 10% of obese youth have hypertension.

DEFINITION OF HYPERTENSION

The definition of hypertension in adults is BP ≥140/90 mm Hg, regardless of body size, sex, or age. This is a functional definition that relates level of BP elevation with the likelihood of subsequent cardiovascular events. Because hypertension-associated cardiovascular events, such as myocardial infarction or stroke, usually do not occur in childhood, the definition of hypertension in children is statistical rather than functional. The National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents published the *Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents* (Fourth Report) in 2004. This report established normal values based on the normative distribution of BP in healthy children and included tables with systolic and diastolic values for the 50th, 90th, 95th, and 99th percentile by age, sex, and height percentile. These normative tables can be obtained online at www.nhlbi.nih.gov/guidelines/hypertension/child_tbl.htm. The Fourth Report defined hypertension as average systolic blood pressure (SBP) and/or diastolic BP that is ≥95th percentile for age, sex, and height on ≥3 occasions. **Prehypertension** was defined as average SBP or diastolic BP that are ≥90th percentile but <95th percentile. In adolescents beginning at age 12 yr, prehypertension is defined as BP between 120/80 mm Hg and the 95th percentile. A child with BP levels

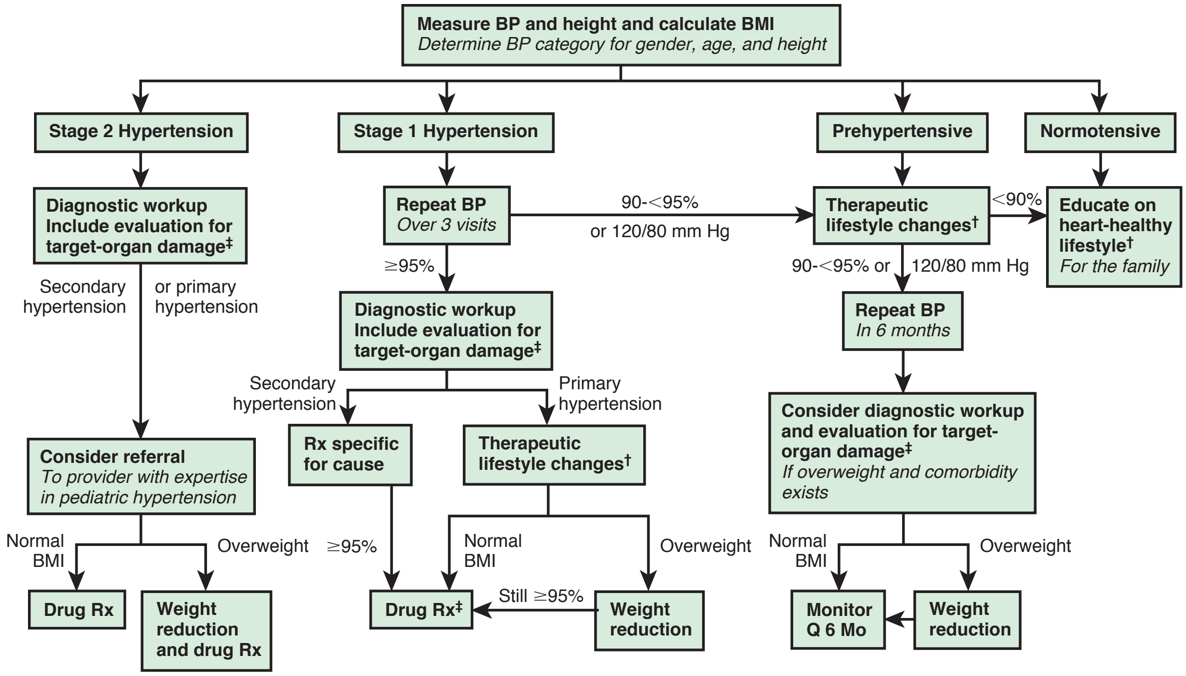

Figure 445-1 Management algorithm. BMI, body mass index; BP, blood pressure; Q, every; Rx, prescription; † diet modification and physical activity; ‡ especially if younger, very high BP, little or no family history, diabetic, or other risk factors. *(From National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents,* Pediatrics *114[2 Suppl 4th Report]:571, 2004.)*

≥95th percentile in a medical setting but normal BP outside of the office has **white coat hypertension.**

The Fourth Report further recommended that if BP is ≥95th percentile, then the hypertension should be staged. Children with BP between the 95th and 99th percentile plus 5 mm Hg are categorized as **stage 1 hypertension,** and children with BP above the 99th percentile plus 5 mm Hg have **stage 2 hypertension**. Stage 1 hypertension, if asymptomatic and without target organ damage, allows time for evaluation before starting treatment, whereas stage 2 hypertension calls for more prompt evaluation and pharmacologic therapy (Fig. 445-1).

MEASUREMENT OF BP IN CHILDREN

The Fourth Report and the American Heart Association recommends that children 3 yr or older should have their BP checked during every healthcare episode (the AHA recommends annual BP checks). Selected children <3 yr old should also have their BP checked, including those with a history of prematurity, congenital heart disease, renal disease, solid-organ transplant, cancer, treatment with drugs known to raise BP, other illnesses associated with hypertension (neurofibromatosis, tuberous sclerosis, others), or evidence of increased intracranial pressure. The preferred method is by auscultation and a BP cuff appropriate for the size of the child's arm should be used. Elevated readings should be confirmed on repeat visits before determining that a child is hypertensive. The BP should be measured with the child in the sitting position after a period of quiet for at least 5 min. Careful attention to cuff size is necessary to avoid over diagnosis, as a cuff that is too short or narrow artificially increases BP readings. A wide variety of bladder sizes should be available in any medical office where children are routinely seen. An appropriate sized cuff has an inflatable bladder that is at least 40% of the arm circumference at a point midway along the upper arm. The inflatable bladder should cover at least two thirds of the upper arm length and 80-100% of its circumference.

Systolic pressure is indicated by appearance of the 1st Korotkoff sound. Diastolic pressure has been defined by consensus as the 5th Korotkoff sound. Palpation is useful for rapid assessment of SBP, although the palpated pressure is generally about 10 mm Hg less than that obtained via auscultation. Oscillometric techniques are used frequently in infants and young children, but they are susceptible to artifacts and are best for measuring mean BP.

Ambulatory blood pressure monitoring (ABPM) is a procedure where the child wears a device that records BP frequently, usually every 20-30 min, throughout a 24 hr period while the child goes about usual daily activities, including sleep. This allows calculation of the mean daytime BP, sleep BP, and mean BP over 24 hr. The physician can also determine the proportion of BP measurements that are in the hypertensive range (BP load) and whether there is an appropriate decrease in BP during sleep (nocturnal dip). ABPM is particularly useful in the evaluation for white coat hypertension and may also be useful for determining risk of hypertensive target organ damage, evaluating resistance to pharmacologic therapy, and evaluating patients with hypotensive episodes on antihypertensive medication. ABPM is also useful for certain special populations, such as children with chronic kidney disease, kidney transplant, and diabetes mellitus where it may provide important information on cardiovascular risk that cannot be determined as well by office measurements.

ETIOLOGY AND PATHOPHYSIOLOGY

BP is the product of cardiac output and peripheral vascular resistance. An increase in either cardiac output or peripheral resistance results in an increase in BP; if 1 of these factors increases while the other decreases, BP may not increase. When hypertension is the result of another disease process, it is referred to as secondary hypertension. When no identifiable cause can be found, it is referred to as primary (essential) hypertension. Many factors, including heredity, diet, stress, and obesity, may play a role in the development of primary hypertension. Secondary hypertension is most common in infants and younger children. The younger the child, the higher the BP and the presence of symptoms related to hypertension, the more likely there will be an underlying secondary cause of hypertension. Many childhood diseases can be responsible for chronic hypertension (Table 445-1) or acute/intermittent hypertension (Table 445-2). The most likely cause varies with age. Hypertension in the premature infant is sometimes associated with umbilical artery catheterization and renal artery thrombosis. Hypertension during early childhood may be caused by renal disease,

coarctation of the aorta, endocrine disorders, or medications. In older school-age children and adolescents, primary hypertension becomes increasingly common.

Secondary hypertension in children is most commonly caused by renal abnormalities; cardiovascular disease or endocrinopathies are additional etiologies. Renal (chronic glomerulonephritis, reflux or obstructive nephropathy, hemolytic uremic syndrome, polycystic or dysplastic renal diseases), or renovascular hypertension, account for approximately 90% of children with secondary hypertension. Renal parenchymal disease and renal artery stenosis lead to water and sodium retention thought to be, in part, secondary to increased renin secretion. Coarctation of the aorta should always be considered. Several endocrinopathies are associated with hypertension, usually those involving the thyroid, parathyroid, and adrenal glands. Systolic hypertension and tachycardia are common in hyperthyroidism; diastolic pressure is not usually elevated. Hypercalcemia, whether secondary to hyperparathyroidism or other causes, often results in mild elevation in BP because of an increase in vascular tone. Adrenocortical disorders (aldosterone-secreting tumors, sodium retaining congenital adrenal hyperplasia, Cushing syndrome) may produce hypertension in patients with increased mineralocorticoid secretion. It is important to consider conditions associated with real or apparent mineralocorticoid excess (Table 445-3) and thus a suppressed renin level form of secondary hypertension. Pheochromocytomas are catecholamine-secreting tumors that give rise to hypertension because of the cardiac and peripheral vascular effects of epinephrine and norepinephrine. Children with pheochromocytoma usually have sustained rather than intermittent or exercise-induced hypertension. Pheochromocytoma develops in approximately 5% of patients with neurofibromatosis. Rarely, secondary hypertension can be caused by pseudohyperaldosteronism, which leads to elevated BP in the face of a suppressed renin level. Such disorders include Liddle syndrome, apparent mineralocorticoid excess, and dexamethasone suppressible aldosteronism. Altered sympathetic tone can be responsible for acute or intermittent elevation of BP in children with Guillain-Barré syndrome, poliomyelitis, burns, and Stevens-Johnson syndrome. Sympathetic outflow from the central nervous system is also affected by intracranial lesions.

A number of drugs of abuse, therapeutic agents, and toxins may cause hypertension. Cocaine may provoke a rapid increase in BP and can

Table 445-3 Clinical Findings in Patients with Mineralocorticoid Excess

CONDITION	CLINICAL PRESENTATION
CAH: 11β-hydroxylase deficiency	Early growth spurt initially, then short adult stature, advanced bone age, premature adrenarche, acne, precocious puberty in males, amenorrhea/hirsutism/virilism in females
CAH: 17α-hydroxylase deficiency	Pseudohermaphroditism (male), sexual infantilism (female)
Apparent mineralocorticoid excess	Growth retardation/short stature, nephrocalcinosis
Liddle syndrome	Severe hypertension, hypokalemia, and metabolic alkalosis, muscle weakness
Geller syndrome	Early onset of hypertension (before age 20 years), exacerbated in pregnancy
Glucocorticoid remediable aldosteronism (GRA) (familial aldosteronism type 1)	Early onset of hypertension, presence of family history of mortality or morbidity from early hemorrhagic stroke
Pseudohypaldosteronism type 2 (Gordon syndrome)	Short stature, hyperkalemic and hyperchloremic metabolic acidosis, borderline blood pressure
Glucocorticoid resistance (children) (Chrousos syndrome)	Ambiguous genitalia, precocious puberty; women may have acne, excessive hair, oligo/anovulation, infertility

From Melcescu E, Phillips J, Moll G, et al: 11 Beta-hydroxylase deficiency and other syndromes of mineralcorticoid excess as a rare cause of endocrine hypertension. Horm Metab Res 44:867-878, 2012 (Table 1, p. 869).

result in seizures or intracranial hemorrhage. Phencyclidine causes transient hypertension that may become persistent in chronic abusers. Tobacco use may also increase BP. Sympathomimetic agents used as nasal decongestants, appetite suppressants, and stimulants for attention deficit disorder produce peripheral vasoconstriction and varying degrees of cardiac stimulation. Individuals vary in their susceptibility to these effects. Oral contraceptives should be suspected as a cause of hypertension in adolescent girls, although the incidence is lower with the use of low-estrogen preparations. Immunosuppressant agents such as cyclosporine and tacrolimus cause hypertension in organ transplant recipients, and the effect is exacerbated by the co-administration of steroids. BP may be elevated in patients with poisoning by a heavy metal.

Children and adolescents with primary (essential) hypertension are commonly overweight, often have a strong family history of hypertension, and usually have BP values at or only slightly above the 95th percentile for age. Primary hypertension is the most common form of hypertension in adults, and it is recognized more often in adolescents than in young children. The cause of primary hypertension is likely to be multifactorial; obesity, genetic alterations in calcium and sodium transport, vascular smooth muscle reactivity, the renin–angiotensin system, sympathetic nervous system overactivity, and insulin resistance have been implicated in this disorder. Elevated uric acid levels may play a role in the pathophysiology of primary hypertension and proof-of-concept studies have confirmed that lowering of uric acid levels results in lower BP in overweight youth with hypertension or prehypertension. Some children and adolescents demonstrate salt-sensitive hypertension, a factor that is ameliorated with weight loss and sodium restriction.

Normotensive children of hypertensive parents may show abnormal physiologic responses that are similar to those of their parents. When subjected to stress or competitive tasks, the offspring of hypertensive adults, as a group, respond with greater increases in heart rate and BP than do children of normotensive parents. Similarly, some children of hypertensive parents may excrete higher levels of urinary catecholamine metabolites or may respond to sodium loading with greater weight gain and increases in BP than do those without a family history of hypertension. The abnormal responses in children with affected parents tend to be greater in the black population than among white individuals.

CLINICAL MANIFESTATIONS

Children and adolescents with primary hypertension are usually asymptomatic; the BP elevation is usually mild and is detected during a routine examination or evaluation before athletic participation. These children may also be obese. Children with secondary hypertension can have BP elevations ranging from mild to severe. Unless the pressure has been sustained or is rising rapidly, hypertension does not usually produce symptoms. Therefore, clinical manifestations may instead reflect the underlying disease process, such as growth failure in children with chronic kidney disease. With substantial hypertension, headache, dizziness, epistaxis, anorexia, visual changes, and seizures may occur. **Hypertensive encephalopathy** (generalized or posterior reversible encephalopathy syndrome) is suggested by the presence of headache, vomiting, temperature elevation, visual disturbances, ataxia, depressed level of consciousness, CT abnormalities, and seizures (Fig. 445-2). Cardiac failure, pulmonary edema, and renal dysfunction (malignant hypertension) may occur in the face of marked hypertension. Bell palsy may be seen in asymptomatic or symptomatic patients. **Hypertensive crisis** may manifest with decreased vision (retinal hemorrhages of hypertensive retinopathy) and papilledema, encephalopathy (headache, seizures, depressed level of consciousness), heart failure, or accelerated deterioration of renal function.

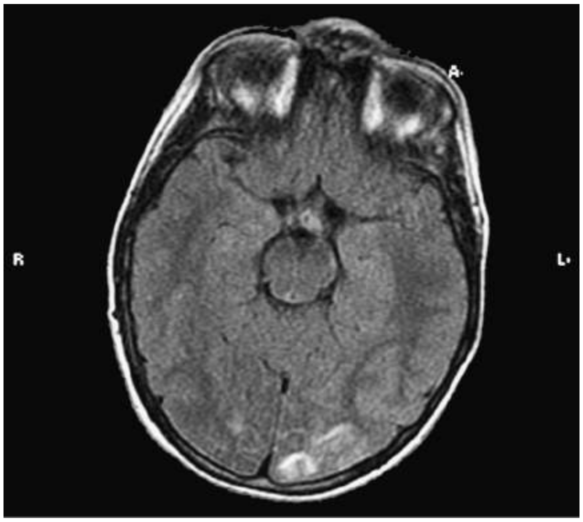

Figure 445-2 Magnetic resonance image of brain of a 6 yr old boy with end-stage renal disease and hypertensive encephalopathy (i.e., posterior reversible leukoencephalopathy syndrome). Bilateral occipital high signal intensity is more pronounced on the left side. *(From Daroff RB, Fenichel GM, Jankovic J, Mazziotta JC, editors,* Bradley's neurology in clinical practice, *ed 6, vol 2, Philadelphia, 2012, Elsevier/Saunders, Fig. 49B.4, p. 924.)*

Subclinical hypertensive target-organ injury is a common clinical manifestation in children with essential hypertension. With the use of

echocardiography using pediatric normative data, left ventricular hypertrophy is detected in up to 40% of hypertensive children. Other markers of target organ damage that have been demonstrated in hypertensive children include increased carotid intima–media thickness, hypertensive retinopathy, and microalbuminuria. Children with prehypertension also have evidence of target organ damage, often at a magnitude intermediate between that of normotensive and hypertensive children.

DIAGNOSIS

The evaluation of the child with chronic hypertension should be directed toward uncovering potential underlying causes of the hypertension, evaluating for comorbidities, and screening for evidence of target organ damage. The extent of the evaluation for underlying causes of hypertension depends on the type of hypertension that is suspected. When secondary hypertension is a strong consideration, as in younger children with severe and symptomatic hypertension, an extensive evaluation may be necessary (Fig. 445-3). Alternatively, overweight adolescents with a family history of hypertension who have mild elevations of BP may need only a limited number of tests.

In all cases, a careful history and physical examination are warranted. A family history for early cardiovascular events should be obtained. Growth parameters should be determined to detect evidence of chronic disease. BP should be obtained in all 4 extremities to detect coarctation (thoracic or abdominal) of the aorta. Table 445-4 identifies other features of the physical examination that may provide evidence of an underlying cause of hypertension. Unless the history and physical examination suggest another cause, children with confirmed hypertension should have an evaluation to detect renal disease, including urinalysis, electrolytes, blood urea nitrogen, creatinine, complete blood count, urine culture, and renal ultrasound. Table 445-5 provides a more complete list of tests to consider in the clinical evaluation of a child with confirmed hypertension. Measuring serum potassium is essential because hypokalemia may be present in Liddle syndrome, glucocorticoid remedial aldosteronism, and apparent mineralcorticoid excess syndrome, while hyperkalemia may be seen in Gordon syndrome.

Renovascular hypertension is often associated with other diseases (Table 445-6) but may be isolated. Magnetic resonance or CT angiography can reveal renal artery stenosis, but fluoroscopic angiography may be needed, especially to detect intrarenal arterial stenosis (Fig. 445-4).

Primary hypertension often clusters with other risk factors. All hypertensive children should be screened for comorbidities that may increase cardiovascular risk, including hyperlipidemia and glucose intolerance. A fasting lipid panel and fasting glucose level should be obtained. In addition, a sleep history should be obtained in children with confirmed hypertension to screen for sleep disordered breathing, an entity that is associated with high BP, particularly in overweight children.

Left ventricular hypertrophy (LVH) is the most common manifestation of target-organ damage in hypertensive children. All children with confirmed hypertension should have echocardiography to evaluate for the presence of LVH. Left ventricular mass measurements should be indexed to height ($m^{2.7}$) to account for the effect of body size. The presence of LVH is an indication to treat the hypertension with pharmacologic therapy.

PREVENTION

Prevention of high BP may be viewed as part of the prevention of cardiovascular disease and stroke, the leading cause of death in adults in the United States. Other risk factors for cardiovascular disease include obesity, elevated serum cholesterol levels, high dietary sodium intake, and a sedentary lifestyle, as well as alcohol and tobacco use. The

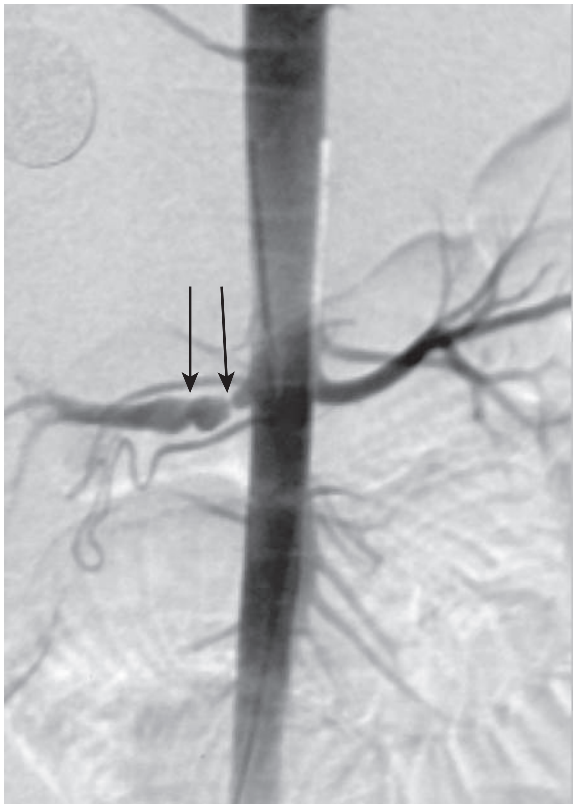

Figure 445-4 Renal angiogram in 7 yr old boy with hypertension. Right renal artery is visible with a string-of-beads appearance characteristic of fibromuscular dysplasia *(arrows)*. The aorta and left renal artery appear normal. *(From Tullus K, Brennan E, Hamilton G, et al: Renovascular hypertension in children,* Lancet *371:1453–1463, 2008, p. 1454, Fig. 1.)*

Table 445-4 Findings to Look for on Physical Examination in Patients with Hypertension

PHYSICAL FINDINGS	POTENTIAL RELEVANCE
GENERAL	
Pale mucous membranes, edema, growth retardation	Chronic renal disease
Elfin facies, poor growth, retardation	Williams syndrome
Webbing of neck, low hairline, widespread nipples, wide carrying angle	Turner syndrome
Moon face, buffalo hump, hirsutism, truncal obesity, striae, acne	Cushing syndrome
HABITUS	
Thinness	Pheochromocytoma, renal disease, hyperthyroidism
Virilization	Congenital adrenal hyperplasia
Rickets	Chronic renal disease
SKIN	
Café-au-lait spots, neurofibromas	Neurofibromatosis, pheochromocytoma
Tubers, "ash-leaf" spots	Tuberous sclerosis
Rashes	Systemic lupus erythematosus, vasculitis (Henoch-Schönlein purpura), impetigo with acute nephritis
Pallor, evanescent flushing, sweating	Pheochromocytoma
Needle tracks	Illicit drug use
Bruises, striae	Cushing syndrome
Acanthosis nigricans	Type 2 diabetes, insulin resistance
EYES	
Extraocular muscle palsy	Nonspecific, chronic, severe
Fundal changes	Nonspecific, chronic, severe
Proptosis	Hyperthyroidism
HEAD AND NECK	
Goiter	Thyroid disease
Adenotonsillar hypertrophy	Sleep disordered breathing
CARDIOVASCULAR SIGNS	
Absent of diminished femoral pulses, low leg pressure relative to arm pressure	Aortic coarctation
Heart size, rate, rhythm; murmurs; respiratory difficulty, hepatomegaly	Aortic coarctation, congestive heart failure
Bruits over great vessels	Arteritis or arteriopathy
Rub	Pericardial effusion secondary to chronic renal disease
PULMONARY SIGNS	
Pulmonary edema	Congestive heart failure, acute nephritis
Picture of bronchopulmonary dysplasia	Bronchopulmonary dysplasia-associated hypertension
ABDOMEN	
Epigastric bruit	Primary renovascular disease or in association with Williams syndrome, neurofibromatosis, fibromuscular dysplasia, or arteritis
Abdominal masses	Wilms tumor, neuroblastoma, pheochromocytoma, polycystic kidneys, hydronephrosis, dysplastic kidneys
NEUROLOGIC SIGNS	
Neurologic deficits	Chronic or severe acute hypertension with stroke
Muscle weakness	Hyperaldosteronism, Liddle syndrome
GENITALIA	
Ambiguous, virilized	Congenital adrenal hyperplasia

increase in arterial wall rigidity and blood viscosity that is associated with exposure to the components of tobacco may exacerbate hypertension. Population approaches to prevention of primary hypertension include a reduction in obesity, reduced sodium intake, and an increase in physical activity through school- and community-based programs.

TREATMENT

The Fourth Report recommended a management algorithm for children with confirmed hypertension according to whether the child has prehypertension, stage 1 hypertension, or stage 2 hypertension (see Figs. 445-1 and 445-5). The mainstay of therapy for children with asymptomatic mild hypertension without evidence of target-organ damage is therapeutic lifestyle modification with dietary changes and regular exercise. Weight loss is the primary therapy in obesity-related hypertension. It is recommended that all hypertensive children have a diet increased in fresh fruits, fresh vegetables, fiber, and nonfat dairy, and reduced in sodium. In addition, regular aerobic physical activity for at least 30-60 min on most days along with a reduction of sedentary activities to less than 2 hr per day is recommended. Indications for pharmacologic therapy include symptomatic hypertension, secondary hypertension, hypertensive target organ damage, diabetes (types 1 and 2), and persistent hypertension despite nonpharmacologic measures (Table 445-7). When indicated, antihypertensive medication should be initiated as a single agent at low dose (see Fig. 445-5). The dose can then be increased until the goal BP is achieved. Once the highest recommended dose is reached or if the child develops side effects, then a second drug from a different class can be added. Acceptable drug classes for use in children include angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, β-blockers, calcium channel blockers, and diuretics. Details on recommended doses of different

Table 445-5 Clinical Evaluation of Confirmed Hypertension

STUDY OR PROCEDURE	PURPOSE	TARGET POPULATION
EVALUATION FOR IDENTIFIABLE CAUSES		
History, including sleep history, family history, risk factors, diet, and habits such as smoking and drinking alcohol; physical examination	History and physical examination help focus subsequent evaluation	All children with persistent BP ≥95th percentile
Blood urea nitrogen, creatinine, electrolytes, urinalysis, and urine culture	R/O renal disease and chronic pyelonephritis, mineralocorticoid excess states	All children with persistent BP ≥95th percentile
Complete blood count	R/O anemia, consistent with chronic renal disease	All children with persistent BP ≥95th percentile
Renal ultrasound	R/O renal scar, congenital anomaly, or disparate renal size	All children with persistent BP ≥95th percentile
EVALUATION FOR COMORBIDITY		
Fasting lipid panel, fasting glucose	Identify hyperlipidemia, identify metabolic abnormalities	Overweight patients with BP at 90th-94th percentile; all patients with BP ≥95th percentile; family history of hypertension or cardiovascular disease; child with chronic renal disease
Drug screen	Identify substances that might cause hypertension	History suggestive of possible contribution by substances or drugs.
Polysomnography	Identify sleep disorder in association with hypertension	History of loud, frequent snoring
EVALUATION FOR TARGET-ORGAN DAMAGE		
Echocardiogram	Identify left ventricular hypertrophy and other indications of cardiac involvement	Patients with comorbid risk factors* and BP 90th-94th percentile; all patients with BP ≥95th percentile
Retinal exam	Identify retinal vascular changes	Patients with comorbid risk factors and BP 90th-94th percentile; all patients with BP ≥95th percentile
ADDITIONAL EVALUATION AS INDICATED		
Ambulatory blood pressure monitoring	Identify white coat hypertension, abnormal diurnal BP pattern, BP load	Patients in whom white coat hypertension is suspected, and when other information on BP pattern is needed
Plasma renin determination	Identify low renin, suggesting mineralocorticoid-related disease	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension Positive family history of severe hypertension
Renovascular imaging Isotopic scintigraphy (renal scan) Magnetic resonance angiography Duplex Doppler flow studies 3-Dimensional CT Arteriography: digital subtraction arteriography or classic	Identify renovascular disease	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension
Plasma and urine steroid levels	Identify steroid-mediated hypertension	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension
Plasma and urine catecholamines	Identify catecholamine-mediated hypertension	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension

R/O, rule out.

*Comorbid risk factors also include diabetes mellitus and kidney disease.

Table 445-7 Recommended Doses for Selected Antihypertensive Agents for Use in Hypertensive Children and Adolescents

CLASS	DRUG	STARTING DOSE	INTERVAL	MAXIMUM DOSE*
Aldosterone receptor antagonist	Eplerenone	25 mg/day	qd-bid	100 mg/day
	Spironolactone[†]	1 $mg\cdot kg^{-1}\cdot day^{-1}$	qd-bid	3.3 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 100 mg/day
Angiotensin-converting enzyme inhibitors	Benazepril[†]	0.2 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 10 mg/day	qd	0.6 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 40 mg/day
	Captopril[†]	0.3-0.5 mg/kg/dose	bid-tid	6 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 450 mg/day
	Enalapril[†]	0.08 $mg\cdot kg^{-1}\cdot day^{-1}$	qd	0.6 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 40 mg/day
	Fosinopril	0.1 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 10 mg/day	qd	0.6 mg/kg/day up to 40 mg/day
	Lisinopril[†]	0.07 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 5 mg/day	qd	0.6 mg/kg/day up to 40 mg/day
	Quinapril	5-10 mg/day	qd	80 mg/day
Angiotensin receptor blockers	Candesartan	1-6 yr, 0.2 $mg\cdot kg^{-1}\cdot day^{-1}$ 6-17 yr, <50 kg 4-8 mg once daily >50 kg 8-16 mg qdqd	qd	1-6 yr, 0.4 mg/kg; 6-17 yr, <50 kg 16 mg qd; >50 kg 32 mg qd
	Losartan[†]	0.75 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 50 mg/day	qd	1.4 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 100 mg/day
	Olmesartan	20 to <35 kg 10 mg qd; ≥35 kg 20 mg qd	qd	20 to <35 kg 20 mg qd ≥35 kg 40 mg qd
	Valsartan[†]	6-17 yr, 1.3 mg/kg/day up to 40 mg/day; <6 yr: 5-10 mg/day	qd	6-17 yr, 2.7 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 160 mg/day; <6 yr: 80 mg/day
α- and β-Adrenergic antagonists	Labetalol[†]	2-3 $mg\cdot kg^{-1}\cdot day^{-1}$	bid	10-12 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 1.2 g/day
	Carvedilol	0.1 mg/kg/dose up to 12.5 mg bid	bid	0.5 mg/kg/dose up to 25 mg bid
β-adrenergic antagonists	Atenolol[†]	0.5-1 $mg\cdot kg^{-1}\cdot day^{-1}$	qd-bid	2 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 100 mg/day
	Bisoprolol/HCTZ	0.04 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 2.5/6.25 mg/day	qd	10/6.25 mg/day
	Metoprolol	1-2 $mg\cdot kg^{-1}\cdot day^{-1}$	bid	6 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 200 mg/day
	Propranolol	1 $mg\cdot kg^{-1}\cdot day^{-1}$	bid-tid	16 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 640 mg/day
Calcium channel blockers	Amlodipine[†]	0.06 $mg\cdot kg^{-1}\cdot day^{-1}$	qd	0.3 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 10 mg/day
	Felodipine	2.5 mg/day	qd	10 mg/day
	Isradipine[†]	0.05-0.15 mg/kg/dose	tid-qid	0.8 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 20 mg/day
	Extended-release nifedipine	0.25-0.5 $mg\cdot kg^{-1}\cdot day^{-1}$	qd-bid	3 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 120 mg/day
Central α-agonist	Clonidine[†]	5-10 µg/kg/day	bid-tid	25 µg/kg/day up to 0.9 mg/day
Diuretics	Amiloride	5-10 mg/day	qd	20 mg/day
	Chlorthalidone	0.3 $mg\cdot kg^{-1}\cdot day^{-1}$	qd	2 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 50 mg/day
	Furosemide	0.5-2.0 mg/kg/dose	qd-bid	6 $mg\cdot kg^{-1}\cdot day^{-1}$
	HCTZ	0.5-1 $mg\cdot kg^{-1}\cdot day^{-1}$	qd	3 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 50 mg/day
Vasodilators	Hydralazine	0.25 mg/kg/dose	tid-qid	7.5 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 200 mg/day
	Minoxidil	0.1-0.2 $mg\cdot kg^{-1}\cdot day^{-1}$	bid-tid	1 $mg\cdot kg^{-1}\cdot day^{-1}$ up to 50 mg/day

bid, Twice-daily; HCTZ, hydrochlorothiazide; qd, once daily; qid, 4 times daily; tid, 3 times daily.

*The maximum recommended adult dose should never be exceeded.

Table 445-8 Antihypertensive Drugs for Management of Severe Hypertension in Children 1–17 Yr

DRUG	CLASS	DOSE	ROUTE	COMMENTS
USEFUL FOR SEVERELY HYPERTENSIVE PATIENTS WITH LIFE-THREATENING SYMPTOMS				
Esmolol	β-Adrenergic blocker	100-500 µg/kg/min	IV infusion	Very short acting—constant infusion preferred. May cause profound bradycardia
Hydralazine	Direct vasodilator	0.2-0.6 mg/kg/dose	IV, IM	Should be given q4h when given IV bolus
Labetalol	α- and β-adrenergic blocker	bolus: 0.20-1.0 mg/kg/dose, up to 40 mg/dose infusion: 0.25-3.0 mg/kg/hr	IV bolus or infusion	Asthma and overt heart failure are relative contraindications
Nicardipine	Calcium channel blocker	Bolus: 30 mcg/kg up to 2 mg/dose Infusion: 0.5-4 µg/kg/min	IV bolus or infusion	May cause reflex tachycardia
Sodium nitroprusside	Direct vasodilator	0.5-10 µg/kg/min	IV infusion	Monitor cyanide levels with prolonged (>72 hr) use or in renal failure; or coadminister with sodium thiosulfate
USEFUL FOR SEVERELY HYPERTENSIVE PATIENTS WITH LESS-SIGNIFICANT SYMPTOMS				
Clonidine	Central α-agonist	0.05-0.1 mg/dose, may be repeated up to 0.8 mg total dose	PO	Side effects include dry mouth and drowsiness
Enalaprilat	ACE inhibitor	5-10 µg/kg/dose up to 1.25 mg/dose	IV bolus	May cause prolonged hypotension and acute renal failure, especially in neonates
Fenoldopam	Dopamine receptor agonist	0.2-0.8 µg/kg/min	IV infusion	Produced modest reductions in BP in a pediatric clinical trial in patients up to 12 yr
Hydralazine	Direct vasodilator	0.25 mg/kg/dose up to 25 mg/dose	PO	Extemporaneous suspension stable for only 1 wk
Isradipine	Calcium channel blocker	0.05-0.1 mg/kg/dose up to 5 mg/dose	PO	Stable suspension can be compounded
Minoxidil	Direct vasodilator	0.1-0.2 mg/kg/dose up to 10 mg/dose	PO	Most potent oral vasodilator; long acting

ACE, angiotensin-converting enzyme, IM, intramuscular, IV, intravenous, PO, oral.

classes of antihypertensive medications for children can be found in the Fourth Report available free online at www.nhlbi.nih.gov/health/prof/heart/hbp/hbp_ped.pdf.

The goal of therapy for hypertension should be to reduce BP below the 95th percentile, except in the presence of chronic kidney disease, diabetes, or target-organ damage, when the goal should be to reduce BP to less than the 90th percentile. Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers should be used for children with diabetes and microalbuminuria or proteinuric renal disease. β-Blockers or calcium channel blockers should be considered for hypertensive children with migraine headaches.

Severe, symptomatic hypertension is a hypertensive emergency that is often accompanied by cardiac failure, retinopathy, renal failure, encephalopathy, and seizures. Intravenous administration is often preferred so that the fall in BP can be carefully titrated (Table 445-8). Drug choices include labetalol, nicardipine, and sodium nitroprusside. Because too rapid a reduction in BP may interfere with adequate organ perfusion, a stepwise reduction in pressure should be planned. In general, the pressure should be reduced by 10% in the 1st hr, and 15% more in the next 3-12 hr, but not to normal during the acute phase of treatment. Hypertensive urgencies, usually accompanied by few serious symptoms such as severe headache or vomiting, can be treated either orally or intravenously. The Fourth Report also includes detailed information on antihypertensive drugs used for the management of severe hypertension in children.

Treatment of secondary hypertension must also focus on the underlying disease such as chronic renal disease, hyperthyroidism, adrenal–genital syndrome, pheochromocytoma, coarctation of the aorta, or renovascular hypertension. The treatment of renovascular stenosis includes antihypertensive medications, angioplasty, or surgery (Fig. 445-6). If bilateral renovascular hypertension or renovascular disease in a solitary kidney is suspected, drugs acting on the renin-angiotensin axis are usually contraindicated because they may reduce glomerular filtration rates and produce renal failure.

Diseases of the Blood

PART XXI

Section 1 The Hematopoietic System

Chapter 446 Development of the Hematopoietic System

Robert D. Christensen and Robin K. Ohls

HEMATOPOIESIS IN THE HUMAN EMBRYO AND FETUS

Hematopoiesis is the process by which the cellular elements of blood are formed. In the developing human embryo and fetus, hematopoiesis is conceptually divided into 3 anatomic stages: mesoblastic, hepatic, and myeloid. Mesoblastic hematopoiesis occurs in extraembryonic structures, principally in the yolk sac, and begins between the 10th and 14th days of gestation. By 6-8 wk of gestation the liver replaces the yolk sac as the primary site of blood cell production, and during this time the placenta also contributes as a hematopoietic site. By 10-12 wk extraembryonic hematopoiesis has essentially ceased. Hepatic hematopoiesis occurs through the remainder of gestation, although hepatic production diminishes during the second trimester while bone marrow (myeloid) hematopoiesis increases. The liver remains the predominant erythropoietic organ (few if any neutrophils are produced in the human fetal liver) through 20-24 wk of gestation.

Each hematopoietic organ houses distinct populations of cells. At 18-20 wk the fetal liver is predominantly an erythropoietic organ, while the marrow produces both erythrocytes and neutrophils. The types of leukocytes present in the fetal liver and marrow differ with gestation. Macrophages precede neutrophils in the marrow, and the ratio of macrophages to neutrophils decreases as gestation progresses. Regardless of gestational age or anatomic location, production of all hematopoietic tissues begins with pluripotent stem cells capable of both self-renewal and clonal maturation into all blood cell lineages. Progenitor cells differentiate under the influence of hematopoietic growth factors (Table 446-1). Fetal hematopoietic growth factor production is independent of maternal growth factor production (Fig. 446-1).

Erythrocytes in the fetus are larger than in adults, and at 22-23 wk gestation the mean corpuscular volume can be as high as 135 fL (Fig. 446-2, *upper panel*). Similarly, the mean corpuscular hemoglobin is very high at 22-23 wk, and falls relatively linearly with advancing gestation (Fig. 446-2, *lower panel*). In contrast, the mean corpuscular hemoglobin concentration is constant throughout gestation at 34±1 g/dL. While the size and quantity of hemoglobin in erythrocytes diminish during gestation, the hematocrit and blood hemoglobin concentration gradually increase (Fig. 446-3, *upper* and *lower panels*, respectively).

Concentrations of platelets in the blood increase gradually between 22 and 40 wk gestation (Fig. 446-4) but the platelet size, assessed by mean platelet volume, remains constant at 8±1 fL. No differences are observed between males and females in fetal and neonatal reference ranges for erythrocyte indices, hematocrit, hemoglobin, platelet counts, or mean platelet volume measurements.

FETAL GRANULOCYTOPOIESIS

Neutrophils are first observed in the human fetus about 5 wk postconception as small clusters of cells around the aorta. The fetal bone marrow space begins to develop around the 8th wk postconception, and from 8-10 wk the marrow space enlarges, but no neutrophils appear there until 10.5 wk. From 14 wk through term, the most common granulocytic cell type in the fetal bone marrow space is the neutrophil. Neutrophils and macrophages originate from a common progenitor cell but macrophages appear prior to neutrophils in the fetus, first in the yolk sac, liver, lung, and brain, all before the bone marrow cavity is formed.

Granulocyte colony-stimulating factor (G-CSF) and macrophage colony-stimulating factor (M-CSF) are expressed in developing fetal bone as early as 6 wk postconception and both are expressed in the fetal liver as early as 8 wk. Granulocyte-macrophage colony-stimulating factor (GM-CSF) and stem cell factor also are distributed widely in human fetal tissues. However, no changes in expression of any of these factors, or of their specific receptors, appear to be the signal for fetal production of neutrophils or macrophages, as those signals have not yet been identified.

Fetal blood contains few neutrophils until the third trimester. At 20 wk gestation the blood neutrophil count is 0-500/mm^3. Although mature neutrophils are scarce, progenitor cells with the capacity to generate neutrophil clones are abundant in fetal blood. When cultured in vitro in the presence of recombinant G-CSF, they mature into large colonies of neutrophils. The physiologic role of G-CSF includes upregulating neutrophil production, and this appears to be the case for the fetus and neonate, as well as for adults. Thus, the low quantities of circulating neutrophils the mid-trimester human fetus may be partly a result of low production of G-CSF. Monocytes isolated from the blood of adults produce G-CSF when stimulated with a variety of inflammatory mediators such as bacterial lipopolysaccharide (LPS) or interleukin (IL)-1. In contrast, monocytes isolated from the blood or organs of fetuses up to 24 wk gestation generate only small quantities of G-CSF protein and messenger RNA (mRNA) after lipopolysaccharide or IL-1 stimulation. Despite this, G-CSF receptors on the surface of neutrophils of newborn infants are equal in number and affinity to those on adult neutrophils.

In the fetus, actions of the granulocytopoietic factors (G-CSF, M-CSF, GM-CSF, and stem cell factor) are not limited to hematopoiesis. Receptors for each of these are located in areas of the fetal central nervous system and gastrointestinal tract, where their patterns of expression change with development. Important developmental roles exist for these factors beyond hematopoiesis.

FETAL THROMBOPOIESIS

Platelet production occurs from 2 pools of cells: megakaryocyte progenitors and megakaryocytes. Megakaryocyte progenitors are categorized as *burst-forming unit–megakaryocytes* (BFU-MK), which are primitive megakaryocyte progenitors, and *colony-forming unit–megakaryocytes* (CFU-MK), which are more differentiated. BFU-MK produce large multifocal colonies containing ≥50 megakaryocytes, whereas CFU-MK generate smaller (3-50 cells/colony) unifocal colonies. The colonies generated by BFU-MK of fetal origin contain significantly more megakaryocytes than do those of adult origin and on that basis are thought to represent somewhat more primitive cells. Megakaryocytes are identified by their morphologic characteristics, as they undergo endoreduplication, which results in large cells with

Table 446-1 Characteristics of Hematopoietic Growth Factors

GROWTH FACTOR	MOLECULAR MASS (kDa)	CHROMOSOMAL LOCATION	PRINCIPAL TARGET CELL
ERYTHROPOIETIN	30-39	7q11-12	CFU-E, fetal BFU-E, endothelial cells, neurons, astrocytes, oligodendrocytes
COLONY-STIMULATING FACTORS			
G-CSF	18-22	17q11.2-21	CFU-G, CFU-MIX, mature neutrophils
GM-CSF	18-30	5q23-31	CFU-MIX, CFU-GM, BFU-E, monocytes, mature neutrophils
M-CSF	45-70 (Dimer of 2 subunits)	5q33.1	CFU-M, macrophages
SCF	36	12q21.32	CFU-MIX, BFU-E, CFU-GM, mast cells
TGF-β	25 Homodimeric protein	19q13.2	BL-CFC
CSF-1	192 Amino acid protein	1p13.3	Monocytes, macrophages, dendritic cells, Langerhans cells
INTERLEUKINS			
IL-1	17	Alpha 2q13 Beta 2q13-21	Hepatocytes, macrophages, lymphocytes
IL-2	15-20	4q26-27	T cells, cytotoxic lymphocytes
IL-3	14-30	5q23-31	CFU-MIX, CFU-Meg, CFU-GM, BFU-E, macrophage
IL-4	16-20	5q23-31	T cells, B cells, dendritic cells
IL-5	46 (Dimer of 2 subunits)	5q23-31	CFU-Eo, B cells
IL-6	19-26	7p21-24	CFU-MIX, CFU-GM, BFU-E, monocytes, B cells, T cells, cytotoxic lymphocytes
IL-7	35	8q12-13	B cells

BFU-E, burst-forming units–erythroid; BL-CFU, blast colony-forming cell; CFU-E, colony-forming units–erythroid; CFU-Eo, colony-forming units–eosinophil; CFU-G, colony-forming units–granulocyte; CFU-GM, colony-forming units–granulocyte macrophage; CFU-M, colony-forming units–macrophage; CFU-Meg, colony-forming units–megakaryocyte; CFU-MIX, colony-forming units–mixed; CSF-1, colony-stimulating factor-1; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; NK, natural killer; SCF, stem cell factor; TGF-β, transforming growth factor-beta.

polyploid nuclei. Megakaryocytes, unlike megakaryocyte progenitors, do not have the capacity to generate clones. Rather, they undergo maturation, progressing from small mononuclear cells to large polyploid cells. The modal megakaryocyte ploidy (the number of sets of complete chromosomes) in normal adult marrow is 16N. In the fetus and neonate, ploidy is lower and megakaryocyte size is smaller. However, umbilical cord blood has a higher concentration of megakaryocytes than adult blood. Large megakaryocytes generate more platelets than do small megakaryocytes; thus, it is assumed that megakaryocytes of neonates produce fewer platelets than do their adult counterparts.

The processes of platelet production and release from megakaryocytes are not well understood. It has been speculated that small buds, proplatelets, are formed on megakaryocytes and that these are released from the marrow as platelets. An alternate possibility is that platelets are principally released from megakaryocytes in the lungs, as a consequence of shear forces.

Thrombopoietin (TPO) is the physiologic regulator of platelet production and acts as a stimulator of all stages of megakaryocyte growth and development (see Table 446-1). The gene encoding TPO is located on the long arm of chromosome 3. TPO-mRNA is expressed primarily in liver and kidney and, to a lesser extent, in marrow stroma. TPO is a primary, but not exclusive, regulator of platelet production and stimulates the proliferation and survival not only of megakaryotic progenitors but also of erythroid, myeloid, and multipotent progenitors. Recombinant TPO supports the growth of megakaryocytic colonies of neonates and children and progenitors of preterm neonates are more sensitive to recombinant TPO than are progenitors of term neonates.

FETAL ERYTHROPOIESIS

Similar to hematopoietic production of other cell lines, fetal erythropoiesis is regulated by growth factors produced by the fetus, not by the mother. Erythropoietin (EPO) does not cross the human placenta. Stimulating maternal EPO production does not stimulate fetal erythropoiesis, and suppressing maternal erythropoiesis by hypertransfusion does not suppress fetal erythropoiesis.

It is unclear to what extent the mechanisms regulating erythropoiesis in adults are operative in the fetus. Of all the factors known to be involved in stimulating erythropoiesis, none plays a more central regulatory role than does EPO, a 30-39 kDa glycoprotein that binds to specific receptors on the surface of erythroid precursors and stimulates their differentiation and clonal maturation into mature

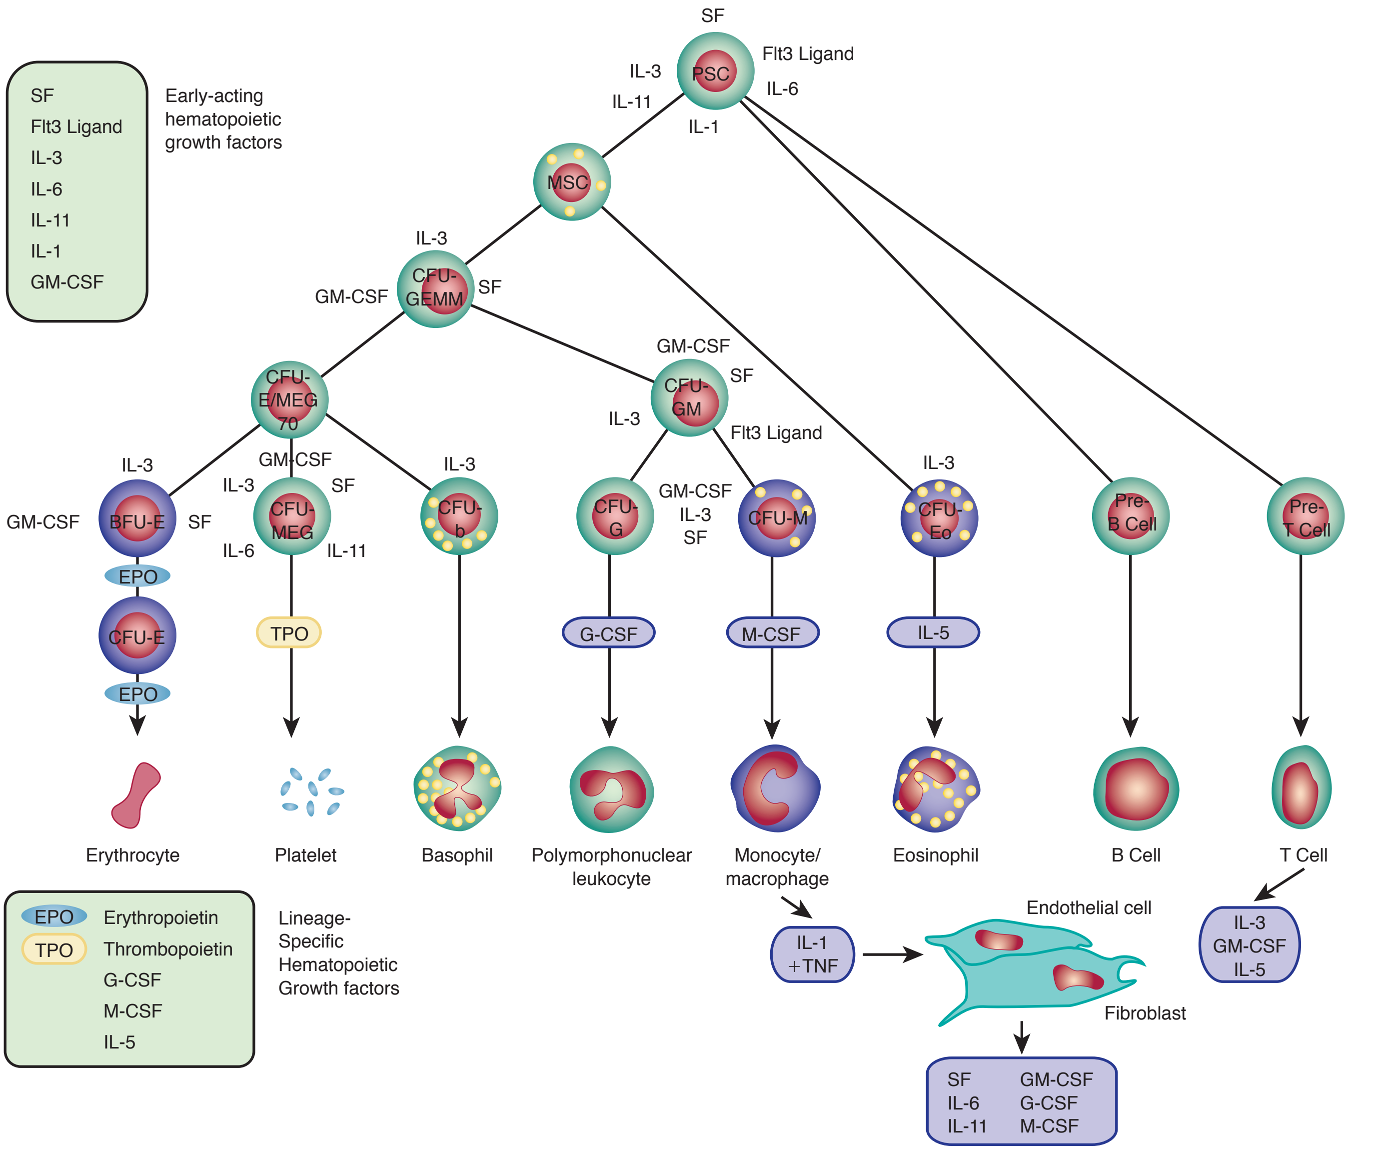

Figure 446-1 **Major cytokine sources and actions to promote hematopoiesis.** Cells of the bone marrow microenvironment, such as macrophages, endothelial cells, and reticular fibroblasts, produce macrophage colony-stimulating factor (M-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF) after stimulation. These cytokines and others listed in the text have overlapping interactions during hematopoietic differentiation, as indicated; for all lineages, optimal development requires a combination of early- and late-acting factors. BFU, burst-forming unit; CFU, colony-forming unit; EPO, erythropoietin; MSC, myeloid stem cells; PSC, pluripotent stem cell. *(From Sieff CA, Nathan DG, Clark SC: The anatomy and physiology of hematopoiesis. In Orkin SH, Nathan DG, editors:* Hematology of infancy and childhood, *ed 5, Philadelphia, 1998, WB Saunders, p. 168.)*

erythrocytes. Regulating EPO gene expression involves an oxygen-sensing mechanism. EPO mRNA production is regulated by *cis*-acting elements in the promoter and 3′ enhancer regions that are responsive to hypoxia. Two factors, hepatic nuclear factor 4 and hypoxia inducible factor (HIF-1), exhibit transcriptional activation for EPO and other hypoxia-inducible genes. Hepatic nuclear factor 4 binds to the EPO promoter and enhancer regions of the gene. HIF-1 is a basic helix-loop-helix transcription factor composed of HIF-1α and HIF-1β subunits that bind to *cis*-acting hypoxia-response elements and induce EPO transcription. HIF-1 is expressed in many cells and is involved in upregulating a variety of oxygen-regulated proteins, including vascular endothelial growth factor. HIF-1α appears to be constitutively expressed and rapidly degraded under normoxic conditions. RNA stability depends on the ubiquitin proteasome degradation system; inhibition of this system leads to increased HIF-1 and increased EPO, even under normoxic conditions.

EPO is produced in fetal liver during the first and second trimesters, principally by cells of monocyte/macrophage origin. After birth, the anatomic site of EPO production shifts to the kidney. The specific stimulus for this shift is unknown but may involve the increase in arterial oxygen tension that occurs at birth. Epigenetic modification of gene expression may also play a role, as it appears that renal and hepatic EPO genes are methylated to different degrees. Although EPO mRNA and protein can be found in the human fetal kidney, it is not known whether this production is biologically relevant. However, it appears that renal production of EPO is not essential for normal fetal erythropoiesis, as evidenced by the normal serum EPO concentrations and normal hematocrits of anephric fetuses.

Hemoglobins in the Fetus and Neonate

The evolutionary development of oxygen-carrying proteins, the **hemoglobins,** increased the ability of blood to transport oxygen. The

combination of oxygen with hemoglobin and its dissociation from hemoglobin are accomplished without expenditure of metabolic energy.

Hemoglobin is a complex protein consisting of iron-containing heme groups and the protein moiety globin. A dynamic interaction between heme and globin gives hemoglobin its unique properties in the reversible transport of oxygen. The hemoglobin molecule is a tetramer made up of 2 pairs of polypeptide chains, with each chain having a heme group attached. The polypeptide chains of various hemoglobins are of chemically different types. The major hemoglobin of a normal adult (HbA) is made up of 1 pair of alpha (α) and 1 pair of beta (β) polypeptide chains, represented as $\alpha_2\beta_2$. The major hemoglobin in the fetus (HbF), which is made up of 2 α- and 2 γ-globin chains, is represented by $\alpha_2\gamma_2$.

The various globin chains differ in both the number and sequence of amino acids, and their synthesis is directed by separate genes (Fig. 446-5). Two sets of genes for the α chains are located on human chromosome 16. Two pairs of alleles provide the genetic information for the structure of the α chain. The β, γ, and δ genes are closely linked on chromosome 11.

Within the red blood cell (RBC) mass of an embryo, fetus, child, and adult, 6 different hemoglobins may normally be detected (Fig. 446-6): the **embryonic hemoglobins,** Gower-1, Gower-2, and Portland; **fetal hemoglobin,** HbF; and the **adult hemoglobins,** HbA and HbA_2. The electrophoretic mobilities of hemoglobins vary with their chemical structures. The time of appearance and quantitative relationships among the hemoglobins are determined by complex developmental processes.

Embryonic Hemoglobins

The blood of early human embryos contains 2 slowly migrating hemoglobins, *Gower-1* and *Gower-2,* and *Hb Portland,* which has HbF-like mobility. The zeta (ζ) chains of Hb Portland and Gower-1 are structurally quite similar to α chains. Both Gower hemoglobins contain a unique type of polypeptide chain, the epsilon (ε) chain. Hb Gower-1 has the structure $\zeta_2\varepsilon_2$, while Gower-2 has the structure $\alpha_2\varepsilon_2$. Hb Portland has the structure $\zeta_2\gamma_2$. In embryos of 4-8 wk gestation, the Gower hemoglobins predominate, but by the 3rd mo they have disappeared.

Fetal Hemoglobin

HbF contains γ polypeptide chains in place of the β chains of HbA. Its resistance to denaturation by strong alkali is the basis for determining the presence of fetal RBCs in the maternal circulation (the **Kleihauer-Betke test**). After the 8th wk, HbF is the predominant hemoglobin; at 24 wk gestation it constitutes 90% of the total hemoglobin. During the 3rd trimester, a gradual decline occurs, so that at birth HbF averages 70% of the total hemoglobin. Synthesis of HbF decreases rapidly postnatally (Fig. 446-7), and by 6-12 mo of age only a trace is present. Less than 2.0% can be detected by alkali denaturation in older children and adults.

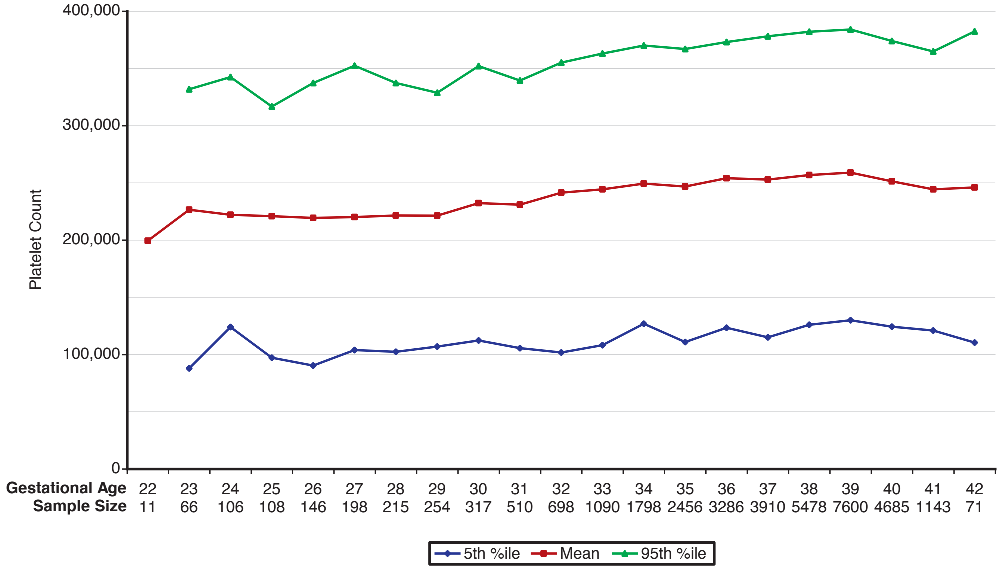

Figure 446-4 **Platelet count from 22 wk gestation through term.** The lines represent the 5th percentile, the mean, and the 95th percentile reference range. *(From Wiedmeier SE, Henry E, Sola-Visner MC, et al: Platelet reference ranges for neonates, defined using data from over 47,000 patients in a multihospital healthcare system,* J Perinatol *29:130–136, 2009.)*

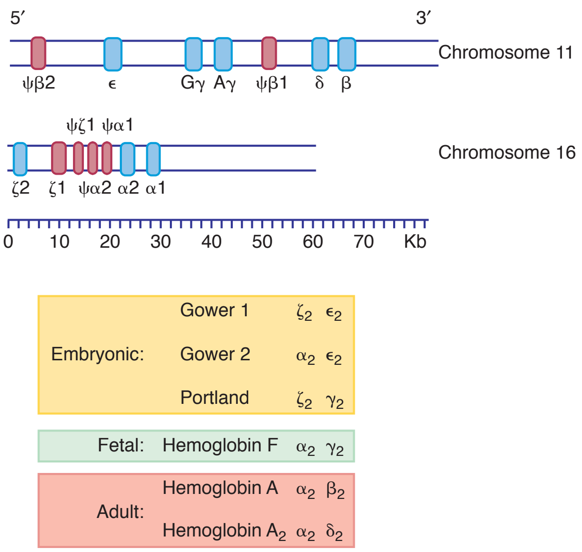

Figure 446-5 **Organization of the globin genes.** The bottom line reflects the scale in kilobases. The upper segment represents the beta-like globin genes on chromosome 11, and the lower segment the alpha-like genes on chromosome 16. Regions of the gene that code for primary globin proteins are shown as blue segments, and regions that code for pseudogenes ("ψ," nonexpressed remnants) are shown as pink segments. The composition of embryonic, fetal, and adult hemoglobins is listed. α, alpha; β, beta; γ, gamma; δ, delta; ε, epsilon; ζ, zeta.

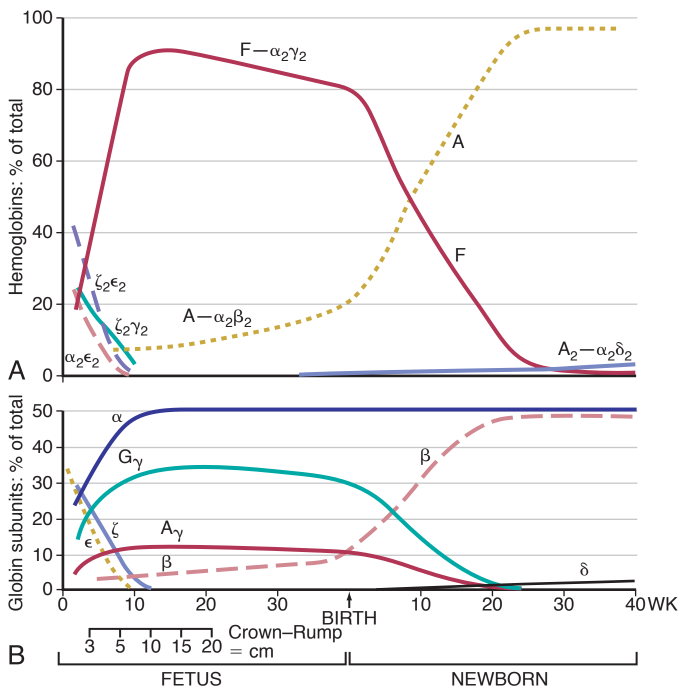

Figure 446-6 **Changes in hemoglobin tetramers (A) and in globin subunits (B) during human development from embryo to early infancy.** *(From Polin RA, Fox WW:* Fetal and neonatal physiology, *ed 2, Philadelphia, 1998, WB Saunders, p. 1769.)*

Adult Hemoglobins

By the 24th wk of gestation, HbA constitutes 5-10% of total hemoglobin. A steady increase follows, so that at term, HbA averages 30%. By 6-12 mo of age, the normal HbA pattern appears. The minor HbA component, HbA_2, contains δ chains and has the structure $\alpha_2\delta_2$. It is seen only when significant amounts of HbA are also present. At birth, <1.0% of HbA_2 is seen, but by 12 mo of age the normal level of 2.0-3.4% is attained. Throughout life, the normal ratio of HbA to HbA_2 is about 30 : 1.

Normal Relationships Among the Hemoglobins

During fetal life and early childhood, the rates of synthesis of γ and β chains and the amounts of HbA and HbF are inversely related. This relationship has been attributed to a "switch mechanism" similar to genetic regulatory mechanisms in bacteria, but the genetic, biologic, and developmental processes that direct a switchover from predominantly γ-chain synthesis in utero to predominantly β-chain synthesis after birth are unclear. It is not certain whether the mechanisms involve selective genetic inhibition or facilitation. The increase in the α_1-globin

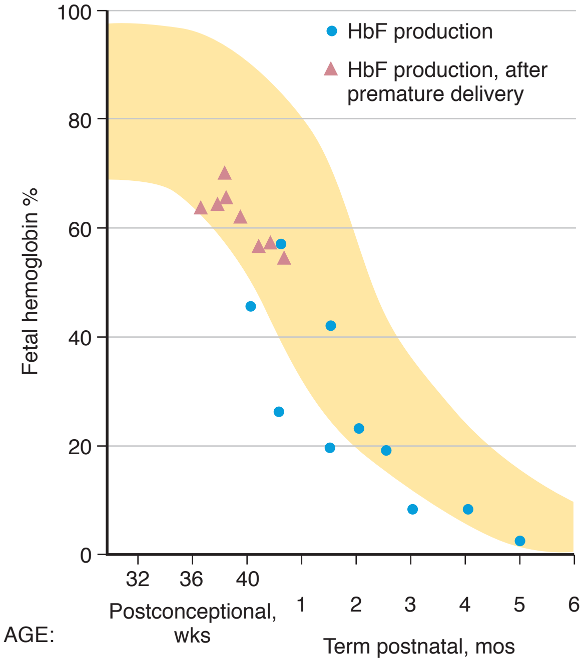

Figure 446-7 **Pre- and postnatal changes in the percentage of total hemoglobin represented by fetal hemoglobin (HbF) (yellow).** The triangles represent postnatal production by reticulocytes in premature infants, and the circles represent cord blood and postnatal reticulocyte production in term infants. *(From Brown MS: Fetal and neonatal erythropoiesis. In Stockman JA, Pochedly C, editors:* Developmental and neonatal hematology, *New York, 1988, Raven Press.)*

to α_2-globin ratio occurring after 36 wk gestation corresponds with a rapid decline in γ-globin synthesis, suggesting that these changes could be regulated by a coordinated molecular mechanism. Differential selection and amplified production of RBC precursors derived from burst-forming unit erythroid cells result in considerable HbF production. This may be the basis for the increased levels of HbF that occur in many hypoproliferative or hemolytic anemias. Alternative explanations involve more basic epigenetic regulation through processes such as methylation and deacetylation in the DNA sequences that flank the hemoglobin gene complexes.

Alterations of the Hemoglobins by Disease

Because hemoglobins containing ε chains normally are present only very early in intrauterine life, in the past they were largely of theoretical interest. Interest has been renewed by the growing method of isolation of free fetal DNA in the maternal circulation, allowing for noninvasive fetal diagnosis of a variety of genetic traits, such as RhD (rhesus antigen D) positivity in the fetus of an RhD negative mother. In addition, small amounts of the Gower hemoglobins have been detectable in a few newborns with trisomy 13. Increased levels of Hb Portland have been found in cord blood of stillborn infants with homozygous α-thalassemia.

HbF levels may be influenced by various factors. Because the HbF level is elevated during the 1st yr of life, knowledge of its normal decline is important (see Figs. 446-6 and 446-7). In persons heterozygous for β-thalassemia (β-thalassemia trait), postpartum decrease of HbF is delayed; approximately 50% of such persons have elevated levels of HbF (>2%) in later life. In homozygous thalassemia (Cooley anemia) and in hereditary persistence of HbF, large amounts of HbF characteristically are found. In patients with major β-chain hemoglobinopathies (HbSS [homozygous hemoglobin S], HbSC [sickle cell hemoglobin C]), HbF usually is increased, particularly during childhood. Preterm infants treated with human recombinant EPO increase HbF production during active erythropoiesis. Moderate elevations of HbF may occur in many diseases accompanied by hematologic stress, such as hemolytic anemias, leukemia, and aplastic anemia, because of a minor population of RBCs that contain increased amounts of HbF. Tetramers of γ chains (γ_4 or Hb Barts) or β chains (β_4, HbH) may be found in α-thalassemia syndromes.

The normal adult level of HbA_2 (2.0-3.4%) is seldom altered. Levels of HbA_2 >3.4% are found in most persons with the β-thalassemia trait and in those with megaloblastic anemias secondary to vitamin B_{12} and folic acid deficiency. Decreased HbA_2 levels are found in those with iron-deficiency anemia (see Chapter 455) and α-thalassemia (see Chapter 462).

RED CELL LIFE SPAN OF THE FETUS AND NEONATE

In general, the highest hematocrit during a person's lifetime occurs at birth, and the lowest occurs about 10 wk later. The reasons for this rapid fall are complex, but a shortened life-span of fetal/neonatal RBC has been suggested as an important component. Specifically, the RBC life span during the fetal and neonatal period is generally thought to be considerably less than the 120 day erythrocyte life span found in normal adults. Estimates of an average 60-90 day life span were derived in the 1960s from studies of chromium (^{51}Cr)-labeled RBC. The "extinction time" is the number of days after transfusing labeled RBC when the label is completely gone from the circulating RBC, thus it estimates the maximal RBC life span. Recent studies indicate that the extinction time of fetal/neonatal RBC is similar to that of adults. For instance, fetal RBC transfused into an ABO-compatible mother, by a fetomaternal transfusion, have an extinction time of 120 days. Moreover, erythrocytes drawn from neonates, labeled with biotin, and transfused back to the neonate, have a half-disappearance time similar to adult donor erythrocytes.

It is possible that some fraction of fetal RBC survive 120 days and are then removed in the spleen by senescence, just as occurs case in healthy adults, while other RBC are removed prematurely by an active process. Neocytolysis is one possibility explaining the active process. Neocytolysis is the active removal of young erythrocytes that were generated in relatively hypoxic conditions, following normoxic or hyperoxic conditions. Neocytolysis is the process whereby the high hematocrit of persons acclimated to high altitude falls rapidly after descent to sea level (a process somewhat analogous to the change from fetal to postbirth oxygen saturations). It will be instructive to determine whether neocytolysis is, indeed, an important regulator of erythrocyte life span and bilirubin production after birth, and whether this process explains the marked fall in hematocrit but a normal RBC "extinction time" in human neonatal physiology.

Chapter **447**

The Anemias

Norma B. Lerner

Anemia is defined as a reduction of the hemoglobin concentration or red blood cell (RBC) volume below the range of values occurring in healthy persons. "Normal" hemoglobin and hematocrit (packed red cell volume) vary substantially with age and sex (Table 447-1). There are also racial differences, with significantly lower hemoglobin levels in African-American children than in white non-Hispanic children of comparable age (Table 447-2). Anemia is a significant global health problem affecting children and reproductive age women (Figs. 447-1 and 447-2).

Physiologic adjustments to anemia include increased cardiac output, augmented oxygen extraction (increased arteriovenous oxygen difference), and a shunting of blood flow toward vital organs and tissues. In

addition, the concentration of 2,3-diphosphoglycerate increases within the RBC. The resultant "shift to the right" of the oxygen dissociation curve reduces the affinity of hemoglobin for oxygen and results in more complete transfer of oxygen to the tissues. The same shift in the oxygen dissociation curve can also occur at high altitude. Higher levels of erythropoietin (EPO) and consequent increased red cell production by the bone marrow further assist the body to adapt.

HISTORY AND PHYSICAL EXAMINATION

As with any medical condition, a detailed history and thorough physical exam are essential when evaluating an anemic child. Important historical facts should include age, sex, race and ethnicity, diet, medications, chronic diseases, infections, travel, and exposures. A family history of anemia and/or associated difficulties such as splenomegaly, jaundice, or early age onset of gallstones is also of consequence. There often are few physical symptoms or signs that result solely from a low hemoglobin, particularly when the anemia develops slowly. Clinical findings generally do not become apparent until the hemoglobin level falls to <7-8 g/dL. Clinical features can include pallor, sleepiness,

irritability, and decreased exercise tolerance. Pallor can involve the tongue, nail beds, palms, or palmar creases. A flow murmur is often present. Ultimately, weakness, tachypnea, shortness of breath on exertion, tachycardia, cardiac dilation, and high-output heart failure will result from increasingly severe anemia, regardless of its cause. Unusual physical findings linked to particular underlying disease etiologies are discussed in detail in sections describing the associated disorders.

LABORATORY STUDIES

Initial laboratory testing should include hemoglobin, hematocrit, and red cell indices as well as a white blood cell count and differential, platelet count, reticulocyte count, and examination of the peripheral blood smear. The need for additional laboratory studies is dictated by the history, the physical, and the results of this initial testing.

DIFFERENTIAL DIAGNOSIS

Anemia is not a specific entity but rather can result from any of number of underlying pathologic processes. To narrow the diagnostic possibilities, anemias may be classified on the basis of their morphology and/or physiology (Fig. 447-3).

Anemias may be morphologically categorized on the basis of RBC size (mean corpuscular volume [MCV]), and microscopic appearance. They can be classified as microcytic, normocytic, or macrocytic based on whether the MCV is low, normal, or high, respectively. RBC size also changes with age, and normal developmental changes in MCV should be recognized before a designation is made (see Table 447-1). Examination of a peripheral blood smear often reveals changes in RBC appearance that will help to further narrow the diagnostic categories (Fig. 447-4). Details regarding morphologic changes associated with particular disorders are described in subsequent sections.

Anemias may also be further divided on the basis of underlying physiology. The 2 major categories are decreased production and increased destruction or loss. The 2 groups are not always mutually exclusive. Decreased RBC production may be a consequence of ineffective erythropoiesis or a complete or relative failure of erythropoiesis. Increased destruction or loss may be secondary to hemolysis, sequestration, or bleeding. The peripheral blood reticulocyte percentage or absolute number will help to make a distinction between the 2 physiologic categories. The normal reticulocyte percentage of total RBCs during most of childhood is approximately 1%, with an absolute reticulocyte count of 25,000-75,000/mm^3. In the presence of anemia, EPO production and the absolute number of reticulocytes should rise. Low or normal numbers of reticulocytes generally represent an inadequate response to anemia that is associated with relative bone marrow failure or ineffective erythropoiesis. Increased numbers of reticulocytes represent a normal bone marrow response to ongoing RBC destruction (hemolysis), sequestration, or loss (bleeding).

Figure 447-3 presents a useful approach to assessing the common causes of anemia in the pediatric age group. Children with microcytic anemia and low or normal reticulocyte counts most often have defects in erythroid maturation or ineffective erythropoiesis. *Iron deficiency* (see Chapter 455) is the most common cause. *Thalassemia trait* (see Chapter 462) constitutes the primary differential diagnosis when iron deficiency is suspected. Distinctions between these entities are presented in Table 455-1 (see Chapter 455). *Chronic disease or inflammation (more often normocytic)*, *lead poisoning, and sideroblastic anemias* should also be considered and are discussed in other chapters. Microcytosis and elevated reticulocyte counts are associated with thalassemia syndromes and hemoglobins C and E (see Chapter 462). Notably, thalassemias and hemoglobinopathies are most commonly seen in patients of Mediterranean, Middle Eastern, African, or Asian descent.

Schwartz.)*

Normocytic anemia and low reticulocyte count characterize a large number of anemias. The *anemia of chronic disease/inflammation* (see Chapter 455) is usually normocytic. The anemia associated with renal failure, primarily a result of reduced EPO production, will invariably be associated with clinical and laboratory evidence of significant kidney disease. Decreased or absent red cell production secondary to transient erythroblastopenia of childhood, infection, drugs, or endocrinopathy usually results in a normocytic anemia, as does bone marrow infiltration by malignancy. In the case of invading leukemia or malignancy, abnormal leukocytes or tumor cells in association with thrombocytopenia or reduced or elevated white cell counts may be seen. Acute bleeding, hypersplenism, and congenital dyserythropoietic anemia type II (see Chapter 452) are also normocytic.

In children with normocytic anemia and an appropriate (high) reticulocyte response, the anemia is usually a consequence of bleeding, hypersplenism, or ongoing hemolysis. In hemolytic conditions, reticulocytosis, indirect hyperbilirubinemia, and increased serum lactate dehydrogenase are indicators of accelerated erythrocyte destruction. There are many causes of hemolysis, resulting from conditions that are extrinsic (usually acquired) or intrinsic (usually congenital) to the red cell. Abnormal RBC morphology (e.g., spherocytes, sickle forms, microangiopathy) identified on the peripheral smear is often helpful in ascertaining the cause.

The anemia seen in children with macrocytic blood cells is sometimes megaloblastic (see Chapter 454), resulting from impaired DNA synthesis and nuclear development. The peripheral blood smear in megaloblastic anemias contains large macroovalocytes, and the neutrophils often show nuclear hypersegmentation. The major causes of megaloblastic anemia include folate deficiency, vitamin B_{12} deficiency, and rare inborn errors of metabolism. Other macrocytic anemias with low or normal reticulocyte counts include acquired and congenital (Diamond-Blackfan and Fanconi) aplastic anemias and hypothyroidism. Patients with trisomy 21 have macrocytic cells, although an accompanying anemia is generally not present. High MCV and reticulocytosis is seen in congenital dyserythropoietic anemias I and III, and in situations wherein hemolysis results in such a large outpouring of young red cells that the mean MCV is abnormally high.

Section 2

Anemias of Inadequate Production

Chapter 448

Congenital Hypoplastic Anemia (Diamond-Blackfan Anemia)

Norma B. Lerner

Diamond-Blackfan anemia (DBA) is a rare, congenital bone marrow failure syndrome that usually becomes symptomatic in early infancy. More than 90% of cases are recognized in the 1st yr of life. The disorder is characterized by anemia, usually normochromic and macrocytic, reticulocytopenia, and insufficient or absent of red blood cell (RBC) precursors in an otherwise normally cellular bone marrow. Up to 50% of affected individuals have additional, extrahematopoietic anomalies.

ETIOLOGY

DBA associated mutations were initially identified in *RPS19,* a gene that encodes a component protein of the small 40S ribosomal subunit. Such *RPS19* mutations, all dominantly inherited, were found to be present in approximately 25% of patients. Nine other DBA genes were subsequently recognized, each encoding a different small (40S) or large (60S) ribosomal subunit protein. Mutations in 1 of the 10 ribosomal

protein (RP) genes were ultimately identified in 50-70% of cases. Although the disorder is often referred to as a **ribosomopathy**, the mechanism by which RP haploinsufficiency leads to DBA has not been fully elucidated. One hypothesis is that unaffected RPs pile up and then bind and inhibit the p53 regulator, MDM_2. This process allows p53 to accumulate, causing cell-cycle arrest and apoptosis of erythroid precursors.

Two distinct mutations in the hematopoietic transcription factor GATA-1 were identified in 2 siblings and 1 unrelated patient with corticosteroid-dependent DBA. It remains unclear whether two pathways, one related to ribosomal dysfunction and one to impaired GATA-1 production, independently cause the same phenotype, or, alternatively that DBA results from problems in a single pathway involving functional links between ribosomes and GATA-1.

EPIDEMIOLOGY

DBA affects about 7 individuals per 1 million live births. It is primarily an autosomal dominant disease, although other inheritance patterns may yet be demonstrated. Notably, there is substantial phenotypic diversity in DBA, even in families whose members share the same mutation, suggesting that additional genetic modifiers affect phenotypic expression of the disease. International consensus recommendations suggest that a diagnosis of "nonclassical" DBA be applied to family members harboring an established mutation or those without a known mutation but with an associated anomaly or laboratory abnormality.

CLINICAL MANIFESTATIONS

Profound anemia usually becomes evident by 2-6 mo of age, occasionally somewhat later. Approximately 25% of patients are anemic at birth and hydrops fetalis occurs rarely; 92% are diagnosed within the first year of life. Approximately 50% of patients have congenital anomalies and more than 1 anomaly is found in 21% of individuals with DBA (Table 448-1). Craniofacial abnormalities are the most common (50% of patients) and include hypertelorism, snub nose, and high arched palate. Skeletal anomalies, mostly upper limb and hand, affect 30% of patients. Thumb abnormalities, including flattening of the thenar eminence and triphalangeal thumb, may be bilateral or unilateral. The radial pulse may be absent. Genitourinary (38% of patients), cardiac (30% of patients), ophthalmologic, and musculoskeletal anomalies have also been identified. Short stature is common, but it is often unclear whether this characteristic results from the disease itself, related therapies, or both.

Table 448-1 Range of Congenital Anomalies Observed in Diamond-Blackfan Anemia

Craniofacial	Hypertelorism Broad, flat nasal bridge Cleft palate High arched palate Microcephaly Micrognathia Microtia Low-set ears Low hair line Epicanthus Ptosis
Ophthalmologic	Congenital glaucoma Strabismus Congenital cataract
Neck	Short neck Webbed neck Sprengel deformity Klippel-Feil deformity
Thumbs	Triphalangeal Duplex or bifid Hypoplastic Flat thenar eminence Absent radial artery
Urogenital	Absent kidney Horseshoe kidney Hypospadias
Cardiac	Ventricular septal defect Atrial septal defect Coarctation of the aorta Complex cardiac anomalies
Other musculoskeletal	Growth retardation Syndactyly
Neuromotor	Learning difficulties

The list includes the anomalies that are most characteristic of DBA but is not exhaustive. Multiple anomalies, most commonly including craniofacial, are present in up to 25% of affected individuals.

From Vlachos A, Ball S, Dahl N, et al: Diagnosing and treating Diamond Blackfan anaemia: results of an international clinical consensus conference. Br J Haematol *142:859–876, 2008 (Table IV, p. 862).*

LABORATORY FINDINGS

The RBCs are usually macrocytic for age, but no hypersegmented neutrophils or other characteristics of megaloblastic anemia are appreciated on the peripheral blood smear. Red cell enzyme patterns are similar to those of a "fetal" RBC population with increased expression of "i" antigen and elevated fetal hemoglobin. Erythrocyte adenosine deaminase (ADA) activity is increased in most patients with this disorder, a finding that helps distinguish congenital RBC aplasia from acquired *transient erythroblastopenia of childhood* (see Chapter 450). Because elevated ADA activity is not a fetal RBC feature, measurement of this enzyme may be particularly helpful when diagnosing DBA in very young infants. Thrombocytosis or, rarely, thrombocytopenia, and occasionally neutropenia, may also be present. Reticulocyte percentages are characteristically very low despite severe anemia. Bone marrow erythrocyte precursors are markedly reduced in most patients; other marrow elements are usually normal. Serum iron levels are elevated. Unlike Fanconi anemia, there is no increase in chromosomal breaks when lymphocytes are exposed to alkylating agents.

DIFFERENTIAL DIAGNOSIS

DBA must be differentiated from other anemias associated with low reticulocyte counts. The syndrome of **transient erythroblastopenia of childhood (TEC)** is often the primary alternative diagnosis. Table 450-1 in Chapter 450 shows a useful comparison of findings in these two disorders. TEC often is differentiated from DBA by its relatively late onset, although it occasionally develops in infants <6 mo of age (see Chapter 450). Macrocytosis, congenital anomalies, fetal red cell characteristics, and elevated erythrocyte ADA are generally associated with DBA and not with TEC.

Other inherited macrocytic bone marrow failure syndromes, particularly Fanconi anemia and Shwachman-Diamond syndrome, should also be considered in the differential as should myelodysplastic syndrome. Hemolytic disease of the newborn can also mimic features of DBA because it can have a protracted course and can be coupled with markedly reduced erythropoiesis. The anemia in this disorder usually resolves spontaneously at 5-8 wk of age. Several types of chronic hemolytic disease may be complicated by an **aplastic crisis**, characterized by reticulocytopenia and decreased numbers of RBC precursors. This event usually occurs after the first several mo of life and is often caused by parvovirus B19 infection (see Chapter 450). Infection with parvovirus B19 (see Chapter 251) in utero also may be associated with pure RBC aplasia in infancy, and even with hydrops fetalis at birth. When diagnosing DBA in young infants, it is important to rule out parvovirus B19 infection using the polymerase chain reaction. Other infections, including HIV, as well as drugs, immune processes, and Pearson syndrome (see Chapter 449) should also be ruled out.

TREATMENT

Corticosteroids are a mainstay of therapy, and approximately 80% of patients initially respond. Because corticosteroids impair linear growth as well as physical and neurocognitive development, many hematologists maintain infants on chronic transfusion therapy and delay the start of steroids until after age 1 yr. Prednisone or prednisolone in doses totaling 2 mg/kg/day is used as an initial trial. An increase in RBC precursors is usually seen in the bone marrow 1-3 wk after therapy is begun and is followed by peripheral reticulocytosis. The hemoglobin can reach normal levels in 4-6 wk, although the rate of response is quite variable. Once it is established that the hemoglobin concentration is increasing, the dose of corticosteroid may be reduced gradually by tapering and then by eliminating all except a single, lowest effective daily dose. This dose may then be doubled, used on alternate days, and tapered still further while maintaining the hemoglobin level at ≥9 g/dL. The target maintenance dose should not exceed 0.5 mg/kg/day or 1 mg/kg every other day. In some patients, very small amounts of prednisone, as low as 2.5 mg twice a wk, may be sufficient to sustain adequate erythropoiesis. Scheduled surveillance examinations and testing for corticosteroid side effects should be pursued in all patients, regardless of dose. Appropriate *Pneumocystis* prophylaxis should be used after the first month of high-dose steroids and continued until the patient is on low-dose alternate-day therapy. Many children with DBA stop taking corticosteroids, usually because of unacceptable side effects or the evolution of corticosteroid refractoriness. Only 37% of patients in the Diamond-Blackfan Anemia Registry (DBAR) (http://www.dbar.org/) remained on corticosteroids.

Patients who are nonresponders or who fail to tolerate corticosteroid therapy require transfusions at intervals of 3-5 wk to maintain a hemoglobin level greater than 8 g/dL. Some younger children may require hemoglobin levels greater than 9 g/dL in order to sustain normal growth and activities. Appropriate screening and, ultimately, the initiation of chelation therapy will be required as excess iron accumulates secondary to repeated transfusions. In one case report, a patient with DBA who was treated with L-leucine became transfusion independent and remained in remission at >5 mo.

Spontaneous remission of anemia with independence from steroid or red cell transfusion therapy has been reported. The likelihood of remission is 25% by age 25 yr, with the majority of patients experiencing remission during the first decade. Mild macrocytic anemia and increased erythrocyte ADA levels persist in these circumstances.

Hematopoietic stem cell transplantation (HSCT) can be curative. As the best outcomes occur using human leukocyte antigen (HLA)-matched sibling donors in patients 9 yr of age or younger. HLA-matched sibling HSCT is recommended in affected, transfusion dependent children between the ages of 3 and 9 yr. It is important that sibling donors be carefully screened, including genotype if known, to ensure that the donor does not carry the patient's DBA gene. Improvements in alternative donor HSCT suggests that this modality may also provide an important option for select patients.

PROGNOSIS

DBA has been identified as a cancer predisposition syndrome. The risk is increased for myelodysplastic syndrome, acute myeloid leukemia, colon carcinoma, osteogenic sarcoma, and female genital cancers. The overall actuarial survival of all patients with DBA is approximately 75% at age 40 yr, with approximately 87% for those maintained on steroids, and approximately 57% for transfusion-dependent patients. Of reported deaths, 67% were treatment related and 22% were DBA-related (malignancy and severe aplastic anemia).

Chapter 449

Pearson Syndrome

Norma B. Lerner

Pearson marrow-pancreas syndrome is a rare mitochondrial disorder that presents with a hypoplastic anemia that may be initially confused with Diamond-Blackfan syndrome or transient erythroblastopenia of childhood. The marrow failure usually appears in the neonatal period and is characterized by a macrocytic anemia and, occasionally, neutropenia and thrombocytopenia. There are vacuolated erythroblasts and myeloblasts in the bone marrow. This disorder is considered a unique variant of **congenital sideroblastic anemia** as the marrow also contains ringed sideroblasts. The hemoglobin F level is elevated. There is multiorgan involvement manifested by failure to thrive and symptoms of exocrine pancreas dysfunction, liver and renal tubular defects, malabsorption, and myopathy. Endocrine dysfunction has also been reported. In rare cases, when the disease is not fatal in early childhood, the disorder may evolve to include symptoms consistent with Kearns-Sayre syndrome.

This disorder is caused by a mitochondrial DNA deletion of variable size and location that is similar to the mitochondrial DNA (mtDNA) deletion found in Kearns-Sayre syndrome. There is heterogeneity in different tissues and between patients, accounting for the variable clinical picture. The proportion of deleted mtDNA in the bone marrow correlates with the severity of the hematologic picture, and a change in the percentage of tissue mtDNA types over time may be associated with spontaneous improvement of red blood cell hypoproliferation. Therapy for the hematologic manifestations of the disease is primarily supportive and includes red cell transfusions to correct anemia and granulocyte colony-stimulating factor to reverse episodes of severe neutropenia.

Chapter 450

Acquired Pure Red Blood Cell Anemia

Norma B. Lerner

TRANSIENT ERYTHROBLASTOPENIA OF CHILDHOOD

Transient erythroblastopenia of childhood (TEC) is the most common *acquired red cell aplasia* occurring in children. It is more prevalent than congenital hypoplastic (Diamond-Blackfan) anemia. This syndrome of severe, transient hypoplastic anemia occurs mainly in previously healthy children between 6 mo and 3 yr of age; most of the children are older than 12 mo at onset. Only 10% of affected patients are >3 yr of age. The annual incidence is estimated to be 4.3 cases per 100,000 children, although it is likely higher, because many cases might go undiagnosed and resolve spontaneously. The suppression of erythropoiesis has been linked to immunoglobulin (Ig) G, IgM, and cell-mediated mechanisms. Familial cases have been reported, suggesting

a hereditary component. TEC often follows a viral illness, although no specific virus has been consistently implicated.

The temporary suppression of erythropoiesis results in reticulocytopenia and moderate to severe normocytic anemia. Some degree of neutropenia occurs in up to 20% of cases. Platelet numbers are normal or elevated. Similar to the situation observed in iron-deficiency anemia and other red blood cell (RBC) hypoplasias, thrombocytosis is presumably caused by increased erythropoietin, which has some homology with thrombopoietin. Mean corpuscular volume (MCV) is characteristically normal for age, and fetal hemoglobin (HbF) levels are normal before the recovery phase. RBC adenosine deaminase levels are normal in this disorder, thus contrasting with the elevation noted in most cases of congenital hypoplastic anemia (Table 450-1). Differentiation from the latter disease is sometimes difficult, but differences in age at onset and in age-related MCV, HbF, and adenosine deaminase are usually helpful. The peak occurrence of TEC coincides with that of iron-deficiency anemia in infants receiving milk as their main caloric source; differences in MCV should help to distinguish between these 2 disorders.

Virtually all children recover within 1-2 mo. RBC transfusions may be necessary for severe anemia in the absence of signs of early recovery. The anemia develops slowly, and significant symptoms usually develop only with severe anemia. Corticosteroid therapy is of no value in this disorder. Any child with presumed TEC who requires >1 transfusion should be reevaluated for another possible diagnosis. In rare instances, a prolonged case of apparent TEC may be caused by parvovirus-induced RBC aplasia, occurring in children with *hemolytic anemia* or *congenital* or *acquired immunodeficiencies*.

Table 450-1 Comparison of Diamond-Blackfan Anemia and Transient Erythroblastopenia of Childhood

FEATURE	DBA	TEC
Male : female	1.1	1.3
AGE AT DIAGNOSIS, MALE (MO)		
Mean	10	26
Median	2	23
Range	0-408	1-120
AGE AT DIAGNOSIS, FEMALE (MO)		
Mean	14	26
Median	3	23
Range	0-768	1-192
Boys >1 yr	9%	82%
Girls >1 yr	12%	80%
Etiology	Genetic	Acquired
Antecedent history	None	Viral illness
Physical examination abnormal (congenital anomalies present)	25%	0%
LABORATORY		
Hemoglobin (g/dL)	1.2-14.8	2.2-12.5
WBCs <5,000/µL	15%	20%
Platelets >400,000/µL	20%	45%
Adenosine deaminase	Increased	Normal
MCV increased at diagnosis	80%	5%
MCV increased during recovery	100%	90%
MCV increased in remission	100%	0%
HbF increased at diagnosis	100%	20%
HbF increased during recovery	100%	100%
HbF increased in remission	85%	0%
i Antigen increased	100%	20%

RED CELL APLASIA ASSOCIATED WITH PARVOVIRUS B19 INFECTION

Parvovirus B19 is a common infectious agent that causes erythema infectiosum (fifth disease) (see Chapter 251). It is also the best-documented viral cause of RBC aplasia in patients with chronic hemolysis, patients who are immunocompromised, and fetuses in utero. This small, nonenveloped single-stranded virus is particularly infective and cytotoxic to marrow erythroid progenitor cells, interacting specifically via binding to the red cell P antigen. In addition to decreased or absent erythroid precursors, characteristic nuclear inclusions in erythroblasts and giant pronormoblasts may be seen under the light microscope in bone marrow specimens. The virus does not cause significant anemia in immunocompetent individuals with normal red cell life spans.

CHRONIC HEMOLYSIS

Because parvovirus infection is usually transient, with recovery occurring in <2 wk, anemia is either not present or not appreciated in otherwise normal children whose peripheral RBC life span is 100-120 days. The RBC life span is much shorter in patients with hemolysis secondary to conditions such as hereditary spherocytosis, immune hemolytic anemia, or sickle cell disease. In these children, a brief cessation of erythropoiesis can cause severe anemia, a condition known as an **aplastic crisis**. When a definitive diagnosis is required, the work-up should include serum parvovirus IgM and IgG titers and, if needed, viral detection using polymerase chain reaction (PCR) techniques. Recovery from moderate to severe anemia is usually spontaneous, heralded by a wave of nucleated RBCs and subsequent reticulocytosis in the peripheral blood. A RBC transfusion may be necessary if the anemia is associated with significant symptoms. Notably, parvovirus-induced aplastic crisis usually occurs only once in children with chronic hemolysis. In families with >1 child affected with a hemolytic disorder, parents should be warned that a similar aplastic episode can occur in the other children if they have not been previously infected.

IMMUNODEFICIENCY

Persistent parvovirus infection may occur in children with congenital immunodeficiency diseases, lymphoproliferative disorders, those being treated with immunosuppressive agents, and those with HIV/AIDS, because these children may be unable to mount an adequate antibody response. The resultant pure RBC aplasia may be severe, and affected children may be thought to have TEC. This type of RBC aplasia differs from TEC in that there is no spontaneous recovery and >1 transfusion is often needed. The diagnosis of parvovirus infection is made by PCR of peripheral blood or bone marrow DNA because the usual serologic responses, reflected by parvovirus serum IgM or IgG titers, are impaired in immunodeficient children. In chronically infected patients, the disease may be treated with high doses of intravenous immunoglobulin, which contains neutralizing antibody to parvovirus and is effective in the short term.

MISCARRIAGE AND HYDROPS FETALIS

Parvovirus infection and destruction of erythroid precursors can also occur in utero. Such events are associated with increased fetal wastage in the first and second trimesters. Infants may be born with hydrops fetalis (see Chapter 103) and anemia. The presence of persistent congenital parvovirus infection is detected by PCR of peripheral blood and/or bone marrow DNA, because immunologic tolerance to the virus can prevent the usual development of specific antibodies.

OTHER RED CELL APLASIAS IN CHILDREN

Acquired red cell aplasia in adults is usually mediated by a chronic antibody and often associated with disorders such as chronic lymphocytic leukemia, lymphoma, thymoma, lymphoproliferative disorders, and systemic lupus erythematosus. This chronic antibody-mediated type of RBC aplasia, often responsive to immunosuppressive therapy,

is quite rare in childhood. Cases of acquired pure red cell aplasia, attributable to T-cell suppression, have also been described.

Certain drugs, such as chloramphenicol, also can inhibit erythropoiesis in a dose-dependent manner. Reticulocytopenia, erythroid hypoplasia, and vacuolated pronormoblasts in the bone marrow are reversible effects of this drug. These effects are distinct from the idiosyncratic and rare development of severe aplastic anemia in chloramphenicol recipients. Acquired antibody-mediated pure red cell aplasia has also been found to be a rare complication in chronic kidney disease patients treated with erythropoiesis-stimulating agents. In addition to discontinuing erythropoiesis-stimulating agents therapy and addressing anemia with red cell transfusions, further treatment may include immunosuppression and renal transplantation.

Chapter 451 Anemia of Chronic Disease and Renal Disease

451.1 Anemia of Chronic Disease

Norma B. Lerner

The anemia of chronic disease (ACD), also referred to as **anemia of inflammation**, is found in conditions where there is ongoing immune activation. It occurs in a wide a range of disorders including infections, malignancies, autoimmunity, and graft-versus-host disease. A similar anemia is associated with chronic kidney disease. ACD is typically a mild to moderate normocytic, normochromic, hypoproliferative anemia associated with a decreased serum iron and low transferrin saturation.

ETIOLOGY

Decreased red cell life span, impaired erythropoiesis, and an increased uptake of iron in the reticuloendothelial system are important mechanisms contributing to the anemia. The modest reduction in erythrocyte longevity is perhaps the least well understood part of the pathophysiology of ACD. Elevated levels of cytokines such as interleukin-1 may increase the macrophage's ability to ingest and destroy erythrocytes. Defective erythropoiesis, both proliferation and differentiation of precursors, has been attributed to immune cell/cytokine-driven inhibition of erythropoietin production and suppression of the bone marrow.

ACD associated alterations in iron recycling is characterized by an accumulation of iron in reticuloendothelial macrophages despite low levels of serum iron. The diversion of iron from the circulation into the reticuloendothelial system results in functional iron deficiency, which results in the impaired heme synthesis and iron-restricted erythropoiesis that contribute to anemia. These alterations in iron metabolism have been attributed to inflammation-associated excess synthesis of **hepcidin**, a key regulatory protein that controls intestinal iron absorption and tissue distribution. Hepcidin, although mainly synthesized by hepatocytes, is also expressed in other cells, including monocytes and macrophages. It functions by binding to and initiating the degradation of the iron exporter, ferroportin.

CLINICAL MANIFESTATIONS

Although the important symptoms and signs associated with ACD are those of the underlying disease, the mild to moderate anemia can affect the patient's quality of life.

LABORATORY FINDINGS

Hemoglobin concentrations are generally 6-9 g/dL. The anemia is usually normochromic and normocytic, although some patients have modest hypochromia and microcytosis, particularly if there is concomitant iron deficiency. Absolute reticulocyte counts are normal or low, and leukocytosis is common. The serum iron level is low, without the increase in serum transferrin that occurs in iron deficiency. This pattern of low serum iron and low-to-normal iron-binding protein (serum transferrin) is a regular and valuable diagnostic feature. *The serum ferritin level may be elevated*. The bone marrow has normal cellularity; the red blood cell precursors are decreased or adequate, marrow hemosiderin may be increased, and granulocytic hyperplasia may be present.

TREATMENT

The best approach to ACD is the treatment, when possible, of the underlying disorder. If the associated systemic disease can be controlled, the anemia will improve or resolve. Transfusions raise the hemoglobin concentration temporarily but are rarely indicated. Erythropoietic stimulating agents (ESAs), such as recombinant human erythropoietin (EPO) or related extended half-life formulations, increase the hemoglobin level and improve activity and the sense of well-being. When using ESAs, treatment with iron is usually necessary to produce optimal effect. Response to these agents is highly variable and poorly responsive patients may require high doses to reach target hemoglobin levels. In adults, such high doses are associated with a higher incidence of adverse events, such as stroke, cardiovascular events, cancer progression, and death, leading the FDA to require a black box warning on labels.

ACD does not respond to iron alone unless there is concomitant deficiency. Unfortunately it is a common clinical challenge to identify iron deficiency in patients with an inflammatory disease (see Chapters 447 and 455). In this circumstance, a trial of iron therapy might be helpful, although there may be no response as persistent inflammation impairs iron absorption and utilization; intravenous iron may further increase hepcidin production. Therapeutic agents that target the hepcidin–ferroportin axis are under investigation.

451.2 Anemia of Renal Disease

Norma B. Lerner

Anemia is common in children with chronic kidney disease (CKD). The anemia is usually normocytic, and the absolute reticulocyte count is normal or low. While most patients with end-stage renal disease (ESRD) are anemic, earlier stages of CKD are associated with a lower prevalence. In adults, lower glomerular filtration rate (GFR) has been correlated with lower hemoglobin concentration, and hemoglobin has been reported to decline below a GFR threshold of 40-60 mL/min/1.73 m^2. In children with CKD, hemoglobin levels decline as the GFR decreases below 43 mL/min/1.73 m^2.

Decreased hemoglobin values are linked to increased incidence of left ventricular hypertrophy, impaired physical activity, and a reduced quality of life in pediatric patients with CKD. In those with ESRD who are on dialysis, anemia is also associated with increased risk of hospitalization and mortality.

ETIOLOGY

Although the anemia of CKD shares many features with the ACD, its predominant cause is decreased EPO production by diseased kidneys. Other important causes include absolute and/or functional iron deficiency as a result of chronic blood loss (from blood sampling, surgeries, and dialysis) and disturbances in the iron metabolic pathway. Higher hepcidin levels have also been implicated in the anemia of CKD. Hepcidin is filtered by the glomerulus and excreted by the kidney; serum concentrations are increased in patients with decreased

GFR. Inflammation may also be a contributing factor in pediatric dialysis patients who have elevated levels of proinflammatory cytokines. Hyperparathyroidism and deficiencies of vitamin B_{12}, folate, and carnitine may also have a role in anemia of CKD.

LABORATORY FINDINGS

Anemia in children with CKD is defined by age: hemoglobin (Hb) <11.0 g/dL (0.5-5 yr), <11.5 g/dL (5-12 yr), <12 g/dL (12-15 yr), <13.0 g/dL (males older than 15 yr), and <12.0 g/dL (females older than 15 yr). The anemia of CKD is hypoproliferative and usually normocytic and normochromic, unless there is concomitant iron deficiency or vitamin deficiency. The EPO level and absolute reticulocyte count are usually low. White cell and platelet counts are generally normal. Ferritin will be low if there is accompanying iron deficiency, and high if there is associated inflammation.

TREATMENT

Oral iron therapy is recommended for all pediatric CKD patients with anemia. Consideration of IV iron therapy may be given for those receiving maintenance hemodialysis. Oral iron at 3-6 mg of elemental iron/kg of target dry weight once daily for 3 mo and possibly IV iron if transferrin saturation (serum iron × 100/total iron-binding capacity) and/or ferritin fail to improve is recommended.

ESAs are the mainstay of therapy and, particularly for children with ESRD, these medications have greatly reduced the need for frequent transfusions, decreasing the incidence of associated iron overload and alloimmunization. It is suggested to start ESA in all children with CKD when Hb concentrations are at 9-10 g/dL, with a goal of 11-12 g/dL (some recommend 11-13 g/dL) for children on maintenance ESA therapy. Dosing varies with age and dialysis modality. Darbepoetin, a synthetic form of EPO, appears to be equally effective as recombinant human EPO and has the benefit of less-frequent dosing as a consequence of a longer half-life. Iron therapy should be continued when using ESAs as treatment demands additional iron for hemoglobin synthesis.

A subset of patients is hyporesponsive to ESAs. In the past, pediatric nephrologists often responded to EPO resistance by further escalating the dose. The increased incidence of adverse events associated with dose escalation in the adult nondialysis CKD patients has prompted some concern about this approach. Several pediatric studies have demonstrated the value of IV iron supplementation in the setting of ESA hyporesponsiveness. In the rare case in which antibody-mediated (to EPO) pure red cell aplasia develops, ESA therapy should be stopped. A study including pediatric hemodialysis patients showed a nearly 50% decrease in hepcidin levels during treatment, suggesting that for those with ESA hyporesponsiveness and iron-restricted erythropoiesis, more frequent or longer duration sessions might be of benefit.

Chapter **452**

Congenital Dyserythropoietic Anemias

Norma B. Lerner

The congenital dyserythropoietic anemias (CDAs) are a heterogeneous class of inherited disorders resulting from abnormalities of late erythropoiesis. These rare conditions are characterized by variable degrees of anemia, ineffective erythropoiesis, and secondary hemochromatosis. Dyserythropoiesis is the major cause of anemia but a shortened half-life of circulating red cells may also contribute. The CDAs have historically been classified into 3 major types (I, II, and II) based upon distinctive bone marrow morphology and clinical features, although additional subgroups and variants have also been identified.

TYPE I CONGENITAL DYSERYTHROPOIETIC ANEMIA

Pathogenesis

Type I CDA is an autosomal recessive disorder. The causative gene *(CDAN1)* was mapped to chromosome 15 between q15.1 and q15.3 and then successfully cloned. The gene encodes codanin-1, which is a ubiquitously expressed protein that may expedite histone assembly into chromatin and regulate the cell cycle. Although the majority of patients with bone marrow characteristics indicative of CDA1 have mutations within *CDAN1,* such mutations have not been detected in approximately 20% of families. Two distinctive mutations in the gene *C15ORF4*, predicted to encode an endonuclease, have been identified in 3 different CDA I pedigrees.

Clinical Manifestations

As of 2011, there were 169 cases from 143 families recorded in the literature. Most families were from Europe and the Middle East. Although CDA I may be diagnosed at any age, most cases are recognized during childhood or adolescence. CDA I is rarely diagnosed in utero. In addition to anemia-related symptoms, other findings often include splenomegaly, jaundice, and hepatomegaly. In more severe cases, evidence of extramedullary hematopoiesis in frontal or parietal bones of the skull and in paravertebral tumors may be present. Cholelithiasis and iron overload develop over time. Type I CDA has been associated with dysmorphic features in 4-14% of cases, primarily involving the digits (syndactyly, absence of nails, supernumerary toes). Retinal angioid streaks and macular abnormalities also have been reported.

Laboratory Findings

Hemoglobin concentrations generally range between 7 and 11 g/dL. The anemia is usually macrocytic (mean corpuscular volume 100-120 fL), but normocytic indices may be seen during childhood. Anisopoikilocytosis is appreciated on the peripheral blood smear. In some cases, normoblasts and basophilic stippling of red blood cells (RBCs) may be seen. The reticulocyte count is inadequate for the degree of anemia. Laboratory evidence of iron overload may be present. The bone marrow aspirate shows erythroid hyperplasia, megaloblastosis, and basophilic stippling. Binucleated and, more rarely, multinucleated polychromatophilic erythroblasts are also appreciated. Incompletely divided cells with thin chromatin bridges between nuclei of pairs of erythrocytes are highly specific for type I CDA. Electron microscopy is the gold standard for diagnosis, revealing erythroblasts with a characteristic "Swiss cheese" heterochromatin pattern.

Treatment

Treatment of this disorder is primarily supportive. Approximately 50% of neonates with CDA I will need at least 1 red cell transfusion and some may remain transfusion dependent over subsequent years. Adolescents and adults may only require episodic transfusions during aplastic crises, infection or pregnancy. If anemia is further exacerbated by coinherited disorders, such as thalassemia or RBC enzymopathy, the patient may become transfusion dependent. The most important long-term complication is **hemosiderosis,** which is caused by increased intestinal absorption of iron and ineffective erythropoiesis; consequently, transfusions should be avoided when possible to prevent further iron loading. Regular phlebotomies result in normal ferritin concentrations but if this approach is untenable oral chelation therapy should be employed when repeated ferritin levels exceed 1000 µg/L. In many cases of documented CDA type I, **interferon-α** has effectively raised the hemoglobin concentration, reduced splenomegaly, and reduced iron overload. *Patients do not respond to erythropoietin.* Splenectomy is generally not

recommended. Cholecystectomy is often required. Allogeneic bone marrow transplantation from a human-leukocyte-antigen-identical sibling has been successful in a few severe cases.

TYPE II CONGENITAL DYSERYTHROPOIETIC ANEMIA

Pathogenesis

CDA II is also an autosomal recessive disorder. Genome-wide linkage analysis identified a region of chromosome 20p11.2 as the location of the candidate *CDAN2* gene that was later identified to be the *SEC23B* gene. This gene is known to encode the cytoplasmic coat protein (COP) II component SEC23B that is involved in endoplasmic reticulum vesicle trafficking. *SEC23B* gene mutations have been associated with the majority of CDA II cases.

Clinical Manifestations

As of 2011, there were 454 cases from 356 families with CDA II recorded, making it the most common form of CDA. Families were mostly from Europe and the Middle East. In contrast to CDA I, this diagnosis is usually made later in life, often because symptoms may be milder. Also, CDA II may be initially misdiagnosed as hereditary spherocytosis. Characteristic findings can include anemia, jaundice, splenomegaly, or hepatomegaly. Posterior mediastinal or paravertebral masses of extramedullary hematopoietic tissue may be noted and signs of iron overload may also be present.

Laboratory Findings

The anemia is normocytic and is generally mild. Hemoglobin levels are lower in children than adults and range between 8 and 11 g/dL. The reticulocyte count, although inadequate, may appear to be normal or increased. Anisopoikilocytosis is noted and occasional basophilic stippling, as well as a few, sometimes binucleate, mature erythroblasts may be found on the peripheral smear. The bone marrow aspirate is normoblastic but hypercellular, with erythroid hyperplasia. In contrast to CDA I, there are many binucleate late polychromatic erythroblasts (10-35%) as well as a few that are multinucleate. Pseudo-Gaucher cells may be present. Electron micrographs show vesicles that are laden with endoplasmic reticulum proteins running beneath the plasma membrane. The pathognomonic finding in type II CDA is that the patient's RBCs lyse in acidified serum because of an immunoglobulin M antibody that recognizes an antigen present on CDA II cells but absent on normal cells. Type II CDA is also known by the acronym **HEMPAS** (*h*ereditary *e*rythroblastic *m*ultinuclearity with a *p*ositive *a*cidified *s*erum test) because it features both erythroblast multinuclearity and circulating RBCs that are sensitive to lysis by acidified normal serum. As this test is technically difficult, the diagnosis is usually made by analyzing red cell membrane proteins via sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). In CDAII there is a thinner band size and faster migration of erythrocyte anion transporter (EA1), or band 3, and band 4.5 proteins.

Treatment

Approximately 10% of patients will require red cell transfusions in infancy and childhood but rarely during adulthood. In contrast to type I CDA, splenectomy may provide hematologic improvement. Splenectomy does not prevent further iron overloading, even in those patients whose hemoglobin is normalized, presumably because of persistent ineffective erythropoiesis in the bone marrow. Like CDA I, secondary hemochromatosis is the most prominent long-term complication and should be approached as outlined above. Allogeneic bone marrow transplantation was successful when pursued in an adult with CDA II and β-thalassemia trait. Most patients can lead a normal life and have a normal life expectancy if complications and consequences are managed appropriately.

TYPE III CONGENITAL DYSERYTHROPOIETIC ANEMIA

Type III CDA is an extremely rare, ill-defined entity, manifested by a mild-to-moderate macrocytic anemia. It is inherited in an autosomal dominant fashion, although there have been cases that might represent de novo mutations or other inheritance patterns. The gene for type III CDA is *KIF23*, which encodes a ubiquitous protein that regulates daughter cell separation during mitosis. In contrast to other CDA types, iron overload is not clinically significant (probably because hemolysis is predominantly intravascular) and spleen size is generally normal. Patients can present with angioid streaks with macular degeneration. The blood smear shows macrocytes, anisopoikilocytosis, and occasional basophilic stippling. The bone marrow is notable for giant erythroid precursors that are often multinucleated, containing up to 12 nuclei per cell. Such multinucleated erythroblasts can also be seen in myelodysplasia and erythroleukemia. Transfusions are usually not required.

Chapter 453

Physiologic Anemia of Infancy

Norma B. Lerner

At birth, normal full-term infants have higher hemoglobin (Hb) levels and larger red blood cells (RBCs) than do older children and adults. However, within the 1st wk of life, a progressive decline in Hb level begins and then persists for 6-8 wk. The resulting anemia is known as the **physiologic anemia of infancy.**

With the onset of respiration at birth, considerably more oxygen becomes available for binding to Hb, and, as a consequence, the Hb–oxygen saturation increases from 50% to 95% or more. There is also a gradual, normal developmental switch from fetal to adult Hb synthesis after birth that results in the replacement of high-oxygen-affinity fetal Hb with lower-affinity adult Hb, capable of delivering more oxygen to tissues. The increase in blood oxygen content and delivery results in the downregulation of erythropoietin (EPO) production, leading to suppression of erythropoiesis. Because there is no erythropoiesis, aged RBCs that are removed from the circulation are not replaced and the Hb level decreases. The Hb concentration continues to decline until tissue oxygen needs become greater than oxygen delivery. Normally, this point is reached between 8 and 12 wk of age, when the Hb concentration is about 11 g/dL. In healthy term infants, the nadir rarely falls below 10 g/dL. At this juncture, EPO production increases and erythropoiesis resumes. The supply of stored reticuloendothelial iron, derived from previously degraded RBCs, remains sufficient for this renewed Hb synthesis, even in the absence of dietary iron intake, until approximately 20 wk of age. In all, this "anemia" should be viewed as a physiologic adaptation to extrauterine life, reflecting the excess oxygen delivery relative to tissue oxygen requirements. There is no hematologic problem, and no therapy is required unless physiologic anemia of infancy is exacerbated by other ongoing processes.

A late **hyporegenerative anemia**, with absence of reticulocytes, can occur in infants with mild hemolytic disease of the newborn. The persistence of maternally derived anti-RBC antibodies in the infant's circulation can lead to an ongoing low-grade hemolytic anemia that can exaggerate the physiologic anemia. Lower-than-expected Hb at the "physiologic" nadir has also been seen in infants after intrauterine or neonatal RBC transfusions. When infants are transfused with adult blood containing HbA, the associated shift of the oxygen dissociation curve facilitates oxygen delivery to the tissues. Accordingly, the definition of anemia and the need for transfusion should be based not only

on the infant's Hb level, but also on oxygen requirements and the ability of circulating RBCs to release oxygen to the tissues.

Premature infants also develop a physiologic anemia, known as *physiologic anemia of prematurity*. The Hb decline is both more extreme and more rapid. Minimal Hb levels of 7-9 g/dL commonly are reached by 3-6 wk of age, and levels may be even lower in very small premature infants (see Chapter 103). The same physiologic factors at play in term infants are operative in preterm infants but are exaggerated. In premature infants, the physiologic Hb decline may be intensified by blood loss from repeated phlebotomies obtained to monitor ill neonates. Demands on erythropoiesis are further heightened by the premature infant's shortened RBC life span (40-60 days) and the accelerated expansion of RBC mass that accompanies the premature baby's rapid rate of growth. Nonetheless, plasma EPO levels are lower than would be expected for the degree of anemia, resulting in a suboptimal erythropoietic response. The reason for diminished EPO levels is not fully understood. During fetal life, EPO synthesis is handled primarily by the liver, whose oxygen sensor is relatively insensitive to hypoxia when compared to the oxygen sensor of the kidney. The developmental switch from liver to kidney EPO production is not accelerated by early birth, and thus the preterm infant must rely on the liver as the primary site for synthesis, leading to diminished responsiveness to anemia. An additional mechanism thought to contribute to diminished EPO levels may be accelerated EPO metabolism. As the pronounced decline in Hb that occurs in many very low birthweight infants is associated with abnormal clinical signs, this "anemia of prematurity" is not considered to be benign and usually requires transfusions.

Some dietary factors, such as folic acid deficiency, can aggravate physiologic anemia. Unless there has been significant blood loss, iron stores should be sufficient to maintain erythropoiesis early on. Vitamin E deficiency does not play a role in anemia of prematurity. Breast milk and infant formulas provide adequate vitamin E.

TREATMENT

In the full-term infant, physiologic anemia requires no therapy beyond ensuring that the infant's diet contains essential nutrients for normal hematopoiesis. In premature infants, an optimal Hb has not been established and is usually dictated by the infant's overall clinical condition. Transfusions may be needed to maintain the Hb at what is considered safe for that child. Premature infants who are feeding well and growing normally rarely need transfusion unless iatrogenic blood loss has been significant. Although factors such as poor weight gain, respiratory difficulties, and abnormal heart rate have prompted transfusion, the beneficial effect has not been documented. Laboratory tests such as blood lactate, EPO, and mixed venous oxygen saturation have poor predictive value. Liberal and restrictive transfusion strategies have been compared in this population. A restrictive strategy does not increase infant morbidity or mortality. In addition, long-term neurodevelopmental outcomes have been found to be poorer in liberally transfused neonates. Late exposure to packed RBC may be related to the development of necrotizing enterocolitis, and early transfusions may be associated with the risk of intraventricular hemorrhage.

When transfusions are necessary, an RBC volume of 10-15 mL/kg is recommended. It is good practice to split units derived from a single donor so that sequential transfusions can be given as required and donor exposure can be minimized. In early preterm infants (weighing <1,250 g), the half-life of transfused RBCs is about 30 days. Delayed cord clamping or umbilical cord milking at birth results in fewer transfusions and a reduction in both intraventricular hemorrhage and necrotizing enterocolitis in preterm infants. Given the impact of phlebotomy losses during monitoring in the neonatal ICU, attention to reducing unnecessary blood draws also has been advocated.

Because premature infants are known to have low plasma EPO levels, recombinant human EPO may be an alternative to transfusion for the treatment of symptomatic preterm infants with anemia of prematurity. In early studies, it was unclear whether EPO reliably reduced donor exposures and reports of adverse effects, such as a possible increase in retinopathy of prematurity, further limited a willingness to use this expensive treatment. One study of preterm infants compared the weekly use of the long-acting agent darbepoetin to triweekly EPO or placebo. Supplemental iron, folate, and vitamin E were provided and the infants were transfused according to an established protocol. Those receiving either EPO or darbepoetin received half the number of transfusions and about half the donors compared with the placebo group. The incidence of mortality, retinopathy, and intracranial hemorrhage was no different between the groups. Nonetheless, this remains an area of controversy.

Chapter 454

Megaloblastic Anemias

Norma B. Lerner

Megaloblastic anemia describes a group of disorders that are caused by impaired DNA synthesis. Red blood cells (RBCs) are larger than normal at every developmental stage, and there is maturational asynchrony between the nucleus and cytoplasm of erythrocytes. The delayed nuclear development becomes increasingly evident as cell divisions proceed. Myeloid and platelet precursors are also affected, and giant metamyelocytes and neutrophil bands are often present in the bone marrow. *There is often an associated thrombocytopenia and leukopenia*. The peripheral blood smear is notable for large, often oval, RBCs with increased mean corpuscular volume. Neutrophils are characteristically hypersegmented, with many having >5 lobes. Most cases of childhood megaloblastic anemia result from a deficiency of folic acid or vitamin B_{12} (cobalamin), vitamins essential for DNA synthesis. Rarely, these anemias may be caused by inborn errors of metabolism. Megaloblastic anemias resulting from malnutrition are relatively uncommon in the United States, but are important worldwide (see Chapters 46 and 447).

454.1 Folic Acid Deficiency

Norma B. Lerner

Folic acid, or pteroylglutamic acid, consists of pteroic acid conjugated to glutamic acid. Biologically active folates are derived from folic acid and serve as 1-carbon donors and acceptors in many biosynthetic pathways. To form functional compounds, folates must be reduced to tetrahydrofolates in a process catalyzed by the enzyme dihydrofolate reductase. As such, they are essential for DNA replication and cellular proliferation. Like other mammals, humans cannot synthesize folate and depend on dietary sources, including green vegetables, fruits, and animal organs (e.g., liver, kidney). Folates are heat labile and water soluble; consequently, boiling or heating folate sources leads to decreased amounts of vitamin. Naturally occurring folates are in a polyglutamated form that is less efficiently absorbed than the monoglutamate species (i.e., folic acid). Dietary folate polyglutamates are hydrolyzed to simple folates that are absorbed primarily in the proximal small intestine by a specific carrier-mediated system. Folates travel in the bloodstream and are taken up in cells primarily in the form of unconjugated methyltetrahydrofolate, which is subsequently reconjugated (polyglutamated) in the cell. There is an active enterohepatic circulation. Although rare, megaloblastic anemia as a consequence of folate deficiency has its peak incidence at 4-7 mo of age, somewhat earlier than iron-deficiency anemia, although both conditions may be present concomitantly in infants with poor nutrition.

ETIOLOGY

Folic acid deficiency can occur as a consequence of inadequate folate intake, decreased folate absorption, or acquired and congenital disorders of folate metabolism or transport.

Inadequate Folate Intake

In the United States, anemia caused by insufficient folate intake usually occurs in the context of increased vitamin requirements associated with pregnancy, periods of accelerated growth, and/or chronic hemolysis. Folate requirements increase markedly during pregnancy, in part to meet fetal needs, and deficiencies are common in mothers, particularly those who are poor or malnourished. Folate supplementation is recommended from the start of pregnancy to prevent neural tube defects and to meet the needs of the developing fetus. Fortunately, folate-deficient mothers generally do not give birth to infants with clinical folate deficiency because there is selective transfer of folate to the fetus via placental folate receptors. Rapid growth after birth increases demands for folic acid and infants who are premature or ill and those with certain hemolytic disorders will have particularly high folate requirements. Human breast milk, infant formulas, and pasteurized cow's milk provide adequate amounts of folic acid. *Goat's milk is deficient*, and supplementation must be given when it is the child's main food. Unless supplemented, powdered milk may also be a poor source of folic acid.

Malnutrition is the most common cause of folate deficiency in older children, and those with hemoglobinopathies, infections, and/or malabsorption are at increased risk. Because body stores of folate are limited, deficiency can develop quickly in malnourished individuals. On a folate-free diet, megaloblastic anemia will occur after 2-3 mo.

Decreased Folate Absorption

Malabsorption caused by chronic diarrheal states or diffuse inflammatory disease can lead to folate deficiency. In both situations, some of the decreased folate absorption may be caused by impaired folate conjugase activity. Chronic diarrhea also interferes with the enterohepatic circulation of folate, thereby enhancing folate losses because of rapid intestinal passage. Megaloblastic anemia because of folic acid deficiency can occur in celiac disease or chronic infectious enteritis and in association with enteroenteric fistulas. Previous intestinal surgery is another potential cause of decreased folate absorption.

Certain anticonvulsant drugs (e.g., phenytoin, primidone, phenobarbital) can impair folic acid absorption, and many patients treated with these drugs have low serum levels. Frank megaloblastic anemia is rare and readily responds to folic acid therapy, even when administration of the offending drug is continued. Alcohol overuse also is associated with folate malabsorption.

Congenital Abnormalities in Folate Transport and Metabolism

Inborn errors of folate transport or metabolism are rare but can be life-threatening. Those associated with megaloblastic anemia include hereditary folate malabsorption and certain extremely uncommon enzyme deficiencies.

Hereditary folate malabsorption (HFM) is an autosomal recessive disorder that is linked to several loss-of-function mutations in the *SLC46A1* gene encoding the protein-coupled folate transporter. HFM is associated with an inability to absorb folic acid, 5-tetrahydrofolate, 5-methyltetrahydrofolate, or 5-formyltetrahydrofolate (folinic acid). It can become apparent at 2-6 mo of age with megaloblastic anemia and other deficits, including infections and diarrhea. Neurologic abnormalities, attributable to folate deficiency in the central nervous system, include seizures, developmental delay, and mental retardation. Folate transport is impaired in both the intestine and at the brain's choroid plexus. Serum and cerebrospinal fluid (CSF) folate levels are very low, with a loss of the normal 3 : 1 ratio of CSF to serum folate.

Treatment, specifically in the context of HFM, usually involves parenteral folate, although oral administration has been useful in some cases. Reduced folates are more effective than folic acid. Folate sufficiency should be maintained in both the blood and the CSF so as to avoid important complications. The megaloblastic anemia in HFM can be reversed with relatively low levels of serum folate, but adequate CSF levels may be quite difficult to achieve, and very large folate doses may be needed.

Functional methionine synthase deficiency may result from mutations affecting the function of methionine synthase reductase or methionine synthase. These disorders are autosomal recessive and are characterized not only by megaloblastic anemia, but also by cerebral atrophy, nystagmus, blindness, and altered muscle tone. Both respond to hydroxocobalamin plus betaine with variable clinical success. Dihydrofolate reductase deficiency is extremely rare and is associated with homozygous mutations in the DHFR gene. Clinical symptoms include megaloblastic anemia and neurologic manifestations. Although **methylenetetrahydrofolate (MTHFR) deficiency** is the most common inborn error of folate metabolism and severe cases can produce a number of neurologic and vascular complications, there is no associated megaloblastic anemia.

Drug-Induced Abnormalities in Folate Metabolism

A number of drugs have anti–folic acid activity as their primary pharmacologic effect and regularly produce megaloblastic anemia. Methotrexate binds to dihydrofolate reductase and prevents formation of tetrahydrofolate, the active form of folate. Pyrimethamine, used in the therapy of toxoplasmosis, and trimethoprim, used for treatment of various infections, can induce folic acid deficiency and, occasionally, megaloblastic anemia. Therapy with folinic acid (5-formyltetrahydrofolate) is usually beneficial.

CLINICAL MANIFESTATIONS

Besides the clinical features associated with anemia, folate-deficient infants and children may manifest irritability, chronic diarrhea, and/or poor weight gain. Hemorrhages from thrombocytopenia may occur in advanced cases. Congenital folate malabsorption and other rare etiologies of folate deficiency may be further associated with hypogammaglobulinemia, severe infections, failure to thrive, neurologic abnormalities, and cognitive delays.

LABORATORY FINDINGS

The anemia is macrocytic (mean corpuscular volume >100 fL). Variations in RBC shape and size are common (see Fig. 447-4B in Chapter 447). The reticulocyte count is low, and nucleated RBCs with megaloblastic morphology are often seen in the peripheral blood. Neutropenia and thrombocytopenia may be present, particularly in patients with long-standing and severe deficiencies. The neutrophils are large, some with hypersegmented nuclei. The bone marrow is hypercellular because of erythroid hyperplasia, and megaloblastic changes are prominent. Large, abnormal neutrophilic forms (giant metamyelocytes) with cytoplasmic vacuolation are also seen.

Normal serum folic acid levels are 5-20 ng/mL; with deficiency, levels are <3 ng/mL. Levels of RBC folate are a better indicator of chronic deficiency. The normal RBC folate level is 150-600 ng/mL of packed cells. Levels of iron and vitamin B_{12} in serum usually are normal or elevated. Serum activity of lactate dehydrogenase, a marker of ineffective erythropoiesis, is markedly elevated.

TREATMENT

When the diagnosis of folate deficiency is established, folic acid may be administered orally or parenterally at 0.5-1.0 mg/day. If the specific diagnosis is in doubt, smaller doses of folate (0.1 mg/day) may be used for 1 wk as a diagnostic test, because a hematologic response can be expected within 72 hr. Doses of folate >0.1 mg can correct the anemia of vitamin B_{12} deficiency but might aggravate any associated neurologic abnormalities. In most medical settings in developed countries, this therapeutic trial to distinguish the different causes of megaloblastic anemia is rarely necessary because vitamin B_{12} and folate blood levels are usually readily available. Folic acid therapy (0.5-1.0 mg/day) should be continued for 3-4 wk until a definite hematologic response has occurred. Maintenance therapy with a multivitamin (containing 0.2 mg of folate) is adequate. As described above, very high doses of

folate may be required in the setting of HFM. Transfusions are indicated only when the anemia is severe or the child is very ill.

Bibliography is available at Expert Consult.

454.2 Vitamin B_{12} (Cobalamin) Deficiency

Norma B. Lerner

Vitamin B_{12}, a generic term encompassing all biologically active cobalamins, is a water-soluble vitamin with a central, functional cobalt atom and a planar corrin ring. Methylcobalamin and adenosylcobalamin are the metabolically active derivatives, serving as cofactors in 2 essential metabolic reactions, namely methylation of homocysteine to methionine (via methionine synthase) and conversion of methyl-malonyl-coenzyme A (CoA) to succinyl CoA (via L-methyl-malonyl-CoA mutase). The products and by-products of these enzymatic reactions are critical to DNA, RNA, and protein synthesis.

Cobalamin is synthesized exclusively by microorganisms and humans must rely on dietary sources (animal products including meat, eggs, fish, and milk) for their needs. Unlike folate, older children and adults have sufficient vitamin B_{12} stores to last 3-5 yr. In young infants born to mothers with low vitamin B_{12} stores, clinical signs of cobalamin deficiency can become apparent in the first 6-18 mo of life.

METABOLISM

Under normal circumstances, cobalamin is released from food protein in the stomach via peptic digestion. Cobalamin then binds to haptocorrin (HC), a salivary glycoprotein. This complex moves into the duodenum, where HC is digested by pancreatic proteases and cobalamin is liberated. Cobalamin then binds to intrinsic factor (IF), another glycoprotein that is produced by gastric parietal cells. The cobalamin-IF complex subsequently enters mucosal cells of the distal ilium by receptor-mediated endocytosis. The IF-cobalamin receptors are composed of a complex of 2 proteins, cubilin (CUBN) and amnionless (AMN), collectively known as cubam. Following internalization into enterocytes, IF is degraded in the lysosome and cobalamin is released. The transporter ABCC1 (also known as MRP1) exports cobalamin bound to the transport protein transcobalamin (TC), out of the cell. In the bloodstream, cobalamin is associated with either TC (approximately 20%) or HC. TC mediates B_{12}'s transport across cells after complexing with the TC receptor, which is internalized in the lysosome. Lysosomal degradation of TC releases cobalamin which remains in the cell where it is further processed. Two distinct membrane proteins transport cobalamin across the lysosomal membrane into the cytoplasm. There cobalamins are processed to a common intermediate that can be allocated to the methylcobalamin and adenosylcobalamin synthesis pathways to meet cellular needs. It is postulated that the MMACHC protein, a product of the cobalamin (Cbl) C locus, accepts the cobalamins exiting the lysosome. A definitive role for HC is yet to be established, but it has been suggested that it plays a role in B_{12} storage.

ETIOLOGY

Vitamin B_{12} deficiency can result from inadequate dietary intake of Cbl, lack of IF, impaired intestinal absorption of IF-Cbl, or absence of vitamin B_{12} transport protein

Inadequate Vitamin B_{12} Intake

B_{12} deficiency in infants is most often nutritional, resulting from low Cbl levels in the breast milk of B_{12}-deficient mothers. Associated megaloblastic anemia often appears during the 1st yr of life. Maternal deficiency may be caused by pernicious anemia or gastrointestinal disorders such as *Helicobacter pylori* infection, celiac disease, Crohn disease, or pancreatic insufficiency. Previous gastric bypass surgery, treatment with proton pump inhibitors, or inadequate intake from a strict vegetarian diet has also been implicated. Fortunately, as a result of active placental Cbl transport in utero, most children of deficient mothers maintain Cbl levels sufficient to support adequate prenatal development. Such infants are born with low stores, the depletion of which is associated with a gradual onset of clinical manifestations. B_{12} replacement often results in rapid improvement, but the longer the deficient period, the greater the likelihood of permanent disabilities. Neonatal screening programs may detect maternal–neonatal nutritional B_{12} deficiency as a result of an increase in propionyl carnitine, but there is higher sensitivity using a measurement of methylmalonic acid. In high-income countries, dietary deficiency during childhood or adolescence is infrequent but can result, as in adults, from strict vegetarian or vegan diet. Daily requirements range from 0.4-2.4 µg.

Impaired Absorption

Gastric surgery or medications that impair gastric acid secretion may result in IF deficiency, leading to decreased vitamin B_{12} absorption. Pancreatic insufficiency can also lead to Cbl deficiency as a consequence of impaired cleavage and IF complex formation. Patients with neonatal necrotizing enterocolitis, inflammatory bowel disease, celiac disease, or surgical removal of the terminal ileum, may also have impaired absorption of vitamin B_{12}. An overgrowth of intestinal bacteria within diverticula or duplications of the small intestine can cause vitamin B_{12} deficiency by consumption of (or competition for) the vitamin or by splitting of its complex with IF. In these cases, hematologic response can follow appropriate antibiotic therapy. In endemic areas, when the fish tapeworm *Diphyllobothrium latum* infests the upper small intestine, similar mechanisms may be operative. When megaloblastic anemia occurs in such situations, the serum vitamin B_{12} level is low and the gastric fluid contains IF.

Hereditary intrinsic factor deficiency (HIFD) is a rare autosomal recessive disorder caused by a variety of mutations in the IF gene that produce a lack of gastric IF or a functionally abnormal IF. It differs from typical adult pernicious anemia in that gastric acid is secreted normally and the stomach is histologically normal. It is not associated with antibodies or endocrine abnormalities. Unlike Imerslund-Grasbeck syndrome (described below), hereditary IF deficiency is only occasionally associated with proteinuria. Symptoms become prominent at an early age (6-24 mo), consistent with exhaustion of vitamin B_{12} stores acquired in utero. As the anemia becomes severe, weakness, irritability, anorexia, and listlessness occur. The tongue is smooth, red, and painful. Neurologic manifestations include ataxia, paresthesias, hyporeflexia, Babinski responses, and clonus. Oral vitamin B_{12} is usually ineffective and lifelong parenteral (IM) Cbl should be used to bypass the absorption defect. The natural form, hydroxocobalamin (OHCbl) is believed to be more effective than the synthetic form, cyanocobalamin (CNCbl). In one retrospective study involving patients with HIFD and Imerslund-Grasbeck syndrome, patients with acute and severe anemia were initially treated with 1 mg of IM OHCbl daily until reticulocyte recovery after which dosing was spaced to once a week. Those without severe anemia were treated with weekly IM OHCbl or CNCbl. With cautious monitoring, all patients were ultimately safely maintained on a schedule of 1 mg of IM OHCbl or CNCbl every 6 mo.

Imerslund-Grasbeck syndrome is a rare, recessively inherited pediatric disorder resulting in selective vitamin B_{12} malabsorption in the ileum, and consequent vitamin B_{12} deficiency. It usually becomes clinically apparent within the first 6 yr of life. In addition to megaloblastic anemia, the patient may also have neurologic defects (such as hypotonia, developmental delay, brain atrophy, movement disorders, and dementia) and/or proteinuria. Patients carry mutations in either CUBN or AMN, proteins that form the cubam receptor for the ileal IF-Cbl complex. Because CUBN is also a key receptor for protein reabsorption in the kidney, impaired expression at this site results in associated proteinuria. The disease can be fatal if it remains untreated. Early diagnosis and treatment with IM Cbl (see treatment for HIFD above) will reverse the hematologic and neurologic abnormalities. Proteinuria does not respond to therapy.

Classic pernicious anemia (autoimmune gastritis) usually occurs in older adults but can rarely affect children. This disorder (juvenile pernicious anemia) usually presents during adolescence. In such cases,

the disease is associated with various detectable antibodies, including those against IF and the hydrogen potassium adenosine triphosphatase proton pump in gastric parietal cells. These children can have additional immunologic abnormalities, cutaneous candidiasis, hypoparathyroidism, and other endocrine deficiencies. There may be atrophy of the gastric mucosa and achlorhydria. Parenteral vitamin B_{12} should be administered regularly.

Absence of Vitamin B_{12} Transport Protein

TC deficiency is a rare cause of megaloblastic anemia. A congenital deficiency is inherited as an autosomal recessive condition resulting in a failure to absorb and transport vitamin B_{12}. Most patients lack TC but some have functionally defective forms. This disorder usually manifests in the first weeks of life. Characteristically, there is failure to thrive, diarrhea, vomiting, glossitis, neurologic abnormalities, and megaloblastic anemia. The diagnosis can be difficult given that total serum vitamin B_{12} levels are often normal because approximately 80% of serum Cbl is bound to HC. The diagnosis is suggested by the presence of severe megaloblastic anemia in the face of normal folate levels and no evidence of any other inborn errors of metabolism. Plasma homocysteine and/or methylmalonic acid levels are elevated. A definitive diagnosis is made by measuring plasma TC. The serum vitamin B_{12} levels must be kept high in order to force enough Cbl into cells to allow normal function. Oral Cbl (CNCbl or OHCbl) 500-1,000 µg twice a wk, or IM OHCbl 1,000 µg per wk, may be used for initial therapy. Symptoms and laboratory studies should be monitored and doses adjusted as needed.

Inborn Errors of Cobalamin Metabolism

The conversion of Cbl to methylcobalamin (MeCbl) and adenosylcobalamin (AdoCbl) involves a number of steps, abnormalities of which have been tied to several distinct alphabetically labeled disorders. In CblE and CblG, defective N5-methyltetrahydrofolate-homocysteine methyltransferase fails to produce MeCbl. Patients present in infancy with megaloblastic anemia, vomiting, and mental retardation, and are found to have homocystinuria and hyperhomocystinemia. They do not have methylmalonic aciduria or methylmalonic acidemia. They show good response to CNCbl. AdoCbl and MeCbl are both affected by CblC (the most common of the Cbl inborn errors), CblD, and CblF. Patients can present in early infancy through adolescence. Newborns have lethargy, failure to thrive, and neurologic problems. Older patients may present with neurologic difficulties, dementia, and psychological problems. Megaloblastic anemia occurs in about half the cases. Patients have elevations of homocysteine and methylmalonic acid in both urine and blood. Affected individuals respond partially to OHCbl or CNCbl. CblA, CblB, and CblH are associated with methylmalonic aciduria and a variety of serious symptoms, but megaloblastic anemia is absent.

CLINICAL MANIFESTATIONS

Children with Cbl deficiency often present with nonspecific manifestations such as weakness, lethargy, feeding difficulties, failure to thrive, and irritability. Other common findings include pallor, glossitis, vomiting, diarrhea, and icterus. Neurologic symptoms can include paresthesia, sensory deficits, hypotonia, seizures, developmental delay, developmental regression, and neuropsychiatric changes. Neurologic problems from vitamin B_{12} deficiency may occur in the absence of any hematologic abnormalities.

LABORATORY FINDINGS

The hematologic manifestations of folate and Cbl deficiency are identical. The anemia resulting from Cbl deficiency is macrocytic, with prominent macro-ovalocytosis of the RBCs (see Fig. 447-2 in Chapter 447). The neutrophils may be large and hypersegmented. In advanced cases, neutropenia and thrombocytopenia can occur, simulating aplastic anemia or leukemia. Serum vitamin B_{12} levels are low, and the serum concentrations of methylmalonic acid and homocysteine are usually elevated. Concentrations of serum iron and serum folic acid are normal or elevated. Serum lactate dehydrogenase activity is markedly increased, a reflection of ineffective erythropoiesis. Moderate elevations of serum bilirubin levels (2-3 mg/dL) also may be found. Excessive excretion of methylmalonic acid in the urine (normal, 0-3.5 mg/24 hr) is a reliable and sensitive index of vitamin B_{12} deficiency.

DIAGNOSIS

A comprehensive medical history is essential to the clinical recognition of possible Cbl deficiency. Information regarding clinical symptoms, dietary history, diseases, surgeries, or medications are likely to provide important clues. The physical exam may reveal relevant findings such as irritability, pallor, or specific neurologic symptoms. Screening laboratory findings (described above) offer important information but more focused testing will be required to confirm a diagnosis of vitamin B_{12} deficiency and its cause. Cbl deficiency is usually identified by measuring total or TC bound vitamin B_{12} in the blood. Although an extremely low level is generally diagnostic, this may not be the case, and false negatives and positives are reportedly common using currently available assays. As a result, it is wise not to discount vitamin B deficiency, particularly in the face of clinical symptoms, macrocytic anemia, an abnormal blood smear, and a normal folate level. In nontreated patients, methylmalonic acid and total homocystine levels are often helpful as they are markedly elevated in the majority of those with clinical signs of B_{12} deficiency. Excessive excretion of methylmalonic acid in the urine (normal: 0-3.5 mg/24 hr) is also a sensitive index of vitamin B_{12} deficiency. Although modest increases occur with renal failure, elevated methylmalonic acid is otherwise quite specific for vitamin B_{12} deficiency. Notably, however, serum homocystine is also elevated in folate deficiency, homocystinuria, and renal failure.

If B_{12} deficiency has been confirmed and there is no evidence of inadequate dietary intake or, in the case of an infant, inadequate maternal B_{12}, malabsorption should be investigated. In the past, the Schilling test, a measure of Cbl absorption, was the gold standard. The test is no longer available and there is currently no comparable replacement for it. Anti–IF antibodies and anti–parietal cell antibodies are useful for the diagnosis of pernicious anemia. Measurement of IF and help from more specialized laboratories may be required for less common disorders.

TREATMENT

Treatment regimens in children have not been well studied. The cause of vitamin B_{12} deficiency should ultimately dictate treatment dosage as well as the duration of therapy. Dose adjustments should be made in response to clinical status and laboratory values. The physiologic requirement for vitamin B_{12} is about 1-3 µg/day. Hematologic responses have been observed with small doses, indicating that administration of a minidose may be used as a therapeutic test when the diagnosis of vitamin B_{12} deficiency is in doubt or in circumstances where the anemia is severe and higher initial doses might result in severe metabolic disturbances.

454.3 Other Rare Megaloblastic Anemias

Norma B. Lerner

Orotic aciduria is a rare autosomal recessive disorder that usually appears in the 1st yr of life and is characterized by growth failure, developmental retardation, megaloblastic anemia, and increased urinary excretion of orotic acid (see Chapter 89). This defect is the most common metabolic error in the de novo synthesis of pyrimidines and therefore affects nucleic acid synthesis. The usual form of hereditary orotic aciduria is caused by a deficiency (in all body tissues) of orotic phosphoribosyl transferase and orotidine-5-phosphate decarboxylase, 2 sequential enzymatic steps in pyrimidine nucleotide synthesis. The diagnosis is suggested by the presence of severe megaloblastic anemia with normal serum B_{12} and folate levels and no evidence of TC deficiency. A presumptive diagnosis is made by finding increased urinary orotic acid. However, confirmation of the diagnosis requires assay of the transferase and decarboxylase enzymes in the patient's

erythrocytes. Physical and mental retardation often accompany this condition. The anemia is refractory to vitamin B_{12} or folic acid, but responds promptly to administration of uridine.

Thiamine-responsive megaloblastic anemia (Rogers syndrome) is a very rare autosomal recessive disorder characterized by megaloblastic anemia, sensorineural deafness, and diabetes mellitus. Congenital heart defects, arrhythmias, visual problems, short stature, tri-lineage myelodysplasia, and strokes are also described. Thiamine-responsive megaloblastic anemia usually presents in infancy but may occasionally develop in childhood and adolescence and occurs in several ethnically distinct populations. The bone marrow is characterized not only by megaloblastic changes but also by ringed sideroblasts. The defect is caused by mutations in the *SCL19A2* gene on chromosome 1, which encodes a high-affinity plasma membrane thiamine transporter. Continuous thiamine supplementation usually reverses the anemia and diabetes but not existing hearing defects.

Chapter 455

Iron-Deficiency Anemia

Richard Sills

Iron deficiency is the most widespread and common nutritional disorder in the world. It is estimated that 30% of the global population has iron-deficiency anemia, and most of them live in developing countries. In the United States, 9% of children ages 12-36 mo are *iron deficient*, and 30% of this group progresses to iron-deficiency *anemia*.

A full-term newborn infant contains about 0.5 g of iron, compared to 5 g of iron in adults. This change in quantity of iron from birth to adulthood means that an average of 0.8 mg of iron must be absorbed each day during the first 15 yr of life. A small additional amount is necessary to balance normal losses of iron by shedding of cells. It is therefore necessary to absorb approximately 1 mg daily to maintain positive iron balance in childhood. Because <10% of dietary iron usually is absorbed, a dietary intake of 8-10 mg of iron daily is necessary to maintain iron levels. During infancy, when growth is most rapid, the approximately 1 mg/L of iron in cow's and breast milk makes it difficult to maintain body iron. Breastfed infants have an advantage because they absorb iron 2-3 times more efficiently than infants fed cow's milk.

ETIOLOGY

Most iron in neonates is in circulating hemoglobin. As the relatively high hemoglobin concentration of the newborn infant falls during the first 2-3 mo of life, considerable iron is recycled. These iron stores are usually sufficient for blood formation in the first 6-9 mo of life in term infants. Stores are depleted sooner in low-birthweight infants or infants with perinatal blood loss because their iron stores are smaller. Delayed (1-3 min) clamping of the umbilical cord can improve iron status and reduce the risk of iron deficiency, whereas early clamping (<30 sec) puts the infant at risk for iron deficiency. Dietary sources of iron are especially important in these infants. In term infants, anemia caused solely by inadequate dietary iron usually occurs at 9-24 mo of age and is relatively uncommon thereafter. The usual dietary pattern observed in infants and toddlers with nutritional iron-deficiency anemia in developed countries is excessive consumption of cow's milk (low iron content, blood loss from milk protein colitis) in a child who is often overweight. Worldwide, undernutrition is usually responsible for iron deficiency.

Blood loss must be considered as a possible cause in every case of iron-deficiency anemia, particularly in older children and adolescents. Chronic iron-deficiency anemia from occult bleeding may be caused by a lesion of the gastrointestinal (GI) tract, such as peptic ulcer, Meckel diverticulum, polyp, hemangioma, or inflammatory bowel disease. Infants can have chronic intestinal blood loss induced by exposure to whole cow's milk protein. This GI reaction is not related to enzymatic abnormalities in the mucosa, such as lactase deficiency, or to an immunoglobulin E–associated milk allergy. Involved infants characteristically develop anemia that is more severe and occurs earlier than would be expected simply from an inadequate intake of iron. The ongoing loss of blood in the stools can be prevented either by breastfeeding or by delaying the introduction of whole cow's milk in the 1st yr of life and then limiting the quantity to <24 oz/24 hr. Unrecognized blood loss also can be associated with chronic diarrhea and, rarely, with pulmonary hemosiderosis. In developing countries, infections with hookworm, *Trichuris trichiura, Plasmodium,* and *Helicobacter pylori* often contribute to iron deficiency. Celiac disease and giardiasis may interfere with iron absorption.

Approximately 2% of adolescent girls have iron-deficiency anemia, largely as a result of their adolescent growth spurt and menstrual blood loss. The highest risk of iron-deficiency anemia (>30%) is among teenagers who are or have been pregnant.

CLINICAL MANIFESTATIONS

Most children with iron deficiency are asymptomatic and are identified by recommended laboratory screening at 12 mo of age, or sooner if at high risk. Pallor is the most important clinical sign of iron deficiency but is not usually visible until the hemoglobin falls to 7-8 g/dL. It is most readily noted as pallor of the palms, palmar creases, nail beds, or conjunctivae. Parents often fail to note the pallor because of the typical slow decline of hemoglobin over time. Often a visiting friend or relative is the first to notice. In mild to moderate iron deficiency (i.e., hemoglobin levels of 6-10 g/dL), compensatory mechanisms, including increased levels of 2,3-diphosphoglycerate and a shift of the oxygen dissociation curve, may be so effective that few symptoms of anemia aside from mild irritability are noted. When the hemoglobin level falls to <5 g/dL, irritability, anorexia, and lethargy develop, and systolic flow murmurs are often heard. As the hemoglobin continues to fall, tachycardia and high output cardiac failure can occur.

Iron deficiency has nonhematologic systemic effects. Both iron deficiency and iron-deficiency anemia are associated with impaired neurocognitive function in infancy. There is also an association of iron-deficiency anemia and later, possibly irreversible, cognitive defects. Although there is support for iron deficiency with or without anemia causing these defects, it has not been established unequivocally. Some studies suggest an increased risk of seizures, strokes, breathholding spells in children, and exacerbations of restless leg syndrome in adults. Given the frequency of iron deficiency and iron-deficiency anemia and the potential for adverse neurodevelopmental outcomes, minimizing the incidence of iron deficiency is an important goal.

Other nonhematologic consequences of iron deficiency include pica, the desire to ingest nonnutritive substances, and **pagophagia,** the desire to ingest ice. The pica can result in the ingestion of lead-containing substances and result in concomitant **plumbism** (see Chapter 721).

LABORATORY FINDINGS

In progressive iron deficiency, a sequence of biochemical and hematologic events occurs (Tables 455-1 and 455-2). First, tissue iron stores are depleted. This depletion is reflected by reduced serum ferritin, an iron-storage protein, which provides an estimate of body iron stores in the absence of inflammatory disease. Next, serum iron levels decrease, the iron-binding capacity of the serum (serum transferrin) increases, and the transferrin saturation falls below normal. As iron stores decrease, iron becomes unavailable to complex with protoporphyrin to form heme. Free erythrocyte protoporphyrins accumulate, and hemoglobin synthesis is impaired. At this point, iron deficiency progresses to iron-deficiency anemia. With less available hemoglobin in each cell, the red cells become smaller and varied in size. The variation in red cell size is measured by an increasing red cell distribution width. This is followed by a decrease in mean corpuscular volume and mean corpuscular hemoglobin. Developmental changes in mean corpuscular

Table 455-1 Indicators of Iron-Deficiency Anemia

INDICATOR	SELECTED CUTOFF VALUES TO DEFINE IRON DEFICIENCY	COMMENTS
Hemoglobin (g/dL)	<11.0 for non-Hispanic whites ages 0.5-4 yr	When used alone, it has low specificity and sensitivity. Use appropriate age specific normal values found in Table 447-1. Normal values for African-Americans are found in Table 447-2.
Mean corpuscular volume (MCV) (μm^3)	<70 from 6-24 months	A reliable, but late indicator of iron deficiency (ID) Low values can also be a result of thalassemia and other causes of microcytosis. Normal values are found in Table 447-1.
Serum ferritin (SF) (µg/L)	≤5 yr <12 Children >5 yr <15 In all age groups in the presence of infection <30	It is probably the most useful laboratory measure of iron stores and helps identify ID; a low value of SF is diagnostic of iron-deficiency anemia (IDA) in a patient with anemia. SF is an acute phase reactant that increases in many acute or chronic inflammatory conditions independent of iron status. Combining SF with a measurement of C-reactive protein (CRP) helps to identify these false-negative SF results.
Reticulocyte hemoglobin content (CHr) (pg)	In infants and young children <27.5 In adults ≤28.0	A sensitive indicator that falls within days of onset of iron-deficient erythropoiesis and is unaffected by inflammation. It is an excellent tool to recognize ID as well as IDA. False normal values can occur when MCV is increased and in thalassemia. It is not yet widely available on hematology analyzers.
Serum transferrin receptor (sTfR)	Cutoff varies with assay and with patient's age and ethnic origin	This soluble receptor is upregulated in ID and is found in increased amounts in serum. It also increased during enhanced erythropoiesis. sTfR is not substantially affected by the acute-phase response, but it might be affected by malaria, age, and ethnicity. Its application is limited by high cost of commercial assays and lack of an international standard, but it has great promise as an indicator of ID.
Transferrin saturation	<16%	It is inexpensive, but its use is limited by diurnal variation in serum iron and by many clinical disorders that affect transferrin concentrations including in inflammatory conditions.
Erythrocyte zinc protoporphyrin (ZPP) (µmol/mol heme)	≤5 yr >70 Children >5 yr >80 Children >5 yr on washed red cells >40	It can be measured directly on a drop of blood with a portable hematofluorometer. A useful screening test in field surveys, particularly in children, in whom uncomplicated ID is the primary cause of anemia. Lead poisoning can increase values, particularly in urban and industrial settings.
Hepcidin	To be defined; usually ≤10 ng/mL	Extremely elevated in anemia of inflammation and suppressed in iron deficiency anemia

Modified from Zimmermann MB, Hurrell RF: Nutritional iron deficiency, Lancet *370:511–520, 2007.*

Table 455-2 Laboratory Studies Differentiating the Most Common Microcytic Anemias

STUDY	IRON-DEFICIENCY ANEMIA	α- OR β-THALASSEMIA	ANEMIA OF CHRONIC DISEASE
Hemoglobin	Decreased	Decreased	Decreased
MCV	Decreased	Decreased	Normal-decreased
RDW	Increased	Normal or minimally increased	Normal-increased
RBC	Decreased	Normal-increased	Normal-decreased
Serum ferritin	Decreased	Normal	Increased
Total Fe binding capacity	Increased	Normal	Decreased
Transferrin saturation	Decreased	Normal	Decreased
FEP	Increased	Normal	Increased
Transferrin receptor	Increased	Normal	Increased
Reticulocyte hemoglobin concentration	Decreased	Normal	Normal-decreased

FEP, free erythrocyte protoporphyrin; MCV, mean corpuscular volume; RBC, red blood cell count; RDW, red cell distribution width.
Modified from Zimmermann MB, Hurrell RF: Nutritional iron deficiency, Lancet *370:511–520, 2007.*

volume require the use of age-related standards for recognizing microcytosis (see Table 447-1). The red blood cell count also decreases. The reticulocyte percentage may be normal or moderately elevated, but absolute reticulocyte counts indicate an insufficient response to the degree of anemia. The blood smear reveals hypochromic, microcytic red cells with substantial variation in cell size. Elliptocytic or cigar-shaped red cells are often seen (Fig. 455-1). Detection of increased soluble transferrin receptor and decreased reticulocyte hemoglobin concentration provide very useful and early indicators of iron deficiency, but their availability is more limited.

White blood cell count is normal, and thrombocytosis is often present. Thrombocytopenia is occasionally seen with iron deficiency,

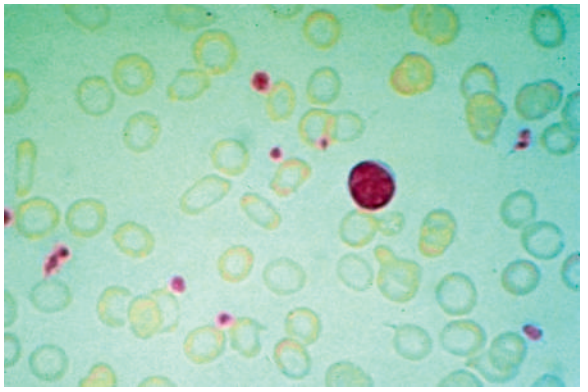

Figure 455-1 Peripheral blood smear from a patient with severe iron-deficiency anemia. The hypochromia is marked. The nucleus of a normal lymphocyte that is comparable in size to a normocytic red cell serves to document many microcytic erythrocytes. The elliptocytic ("cigar-forms") red cells are typical of iron deficiency. Note the variation in red cell size. *(Courtesy of the University of Washington/American Society of Hematology Slide Bank.)*

potentially confusing the diagnosis with bone marrow failure disorders. Stool for occult blood should be checked to exclude blood loss as the cause of iron deficiency.

A presumptive diagnosis of iron-deficiency anemia is most often made by a complete blood count demonstrating a microcytic anemia with a high red cell distribution width, reduced red blood cell count, normal white blood cell count, and normal or elevated platelet count. Other laboratory studies, such as reduced serum ferritin, reduced serum iron, and increased total iron-binding capacity, are not usually necessary unless severe anemia requires a more rapid diagnosis, other complicating clinical factors are present, or the anemia does not respond to iron therapy. An increase in hemoglobin ≥1 g/dL after a month of iron therapy is usually the most practical means to establish the diagnosis.

A diagnosis of iron deficiency in the absence of anemia is more challenging. Serum ferritin is a useful measure whose value is increased by also measuring C-reactive protein to help identify false negative results because of concomitant inflammation. Detection of increased soluble transferrin receptor and decreased reticulocyte hemoglobin concentration may find increasing use as they become more available.

DIFFERENTIAL DIAGNOSIS

The most common alternative causes of microcytic anemia are α- or β-thalassemia and other hemoglobinopathies, including hemoglobins E and C (see Chapter 462.9). The anemia of inflammation is usually normocytic but can be microcytic in a minority of cases (see Chapter 451.1). Lead poisoning can cause microcytic anemia, but more often the microcytic anemia is due to iron deficiency causing pica and secondary lead intoxication (see Chapter 721). Table 455-2 compares the use of laboratory studies in the diagnosis of the most common microcytic anemias. Other etiologies of microcytic anemia are found in Table 455-3. Although the platelet count can be abnormal, the white blood cell count and neutrophil count should be normal.

When anemia is identified solely by hemoglobin or hematocrit, 60% of children in developed countries have anemia not because of iron deficiency. Caution should be used in treating these children with iron without the benefit of a complete blood and differential count to ensure that a more serious diagnosis is not missed.

PREVENTION

Iron deficiency is best prevented to avoid both its systemic manifestations and the anemia. Breastfeeding should be encouraged, with the addition of supplemental iron at 4 mo of age. Infants who are not breastfed should only receive iron-fortified formula (12 mg of iron per liter) for the first year, and thereafter cow's milk should be limited to <20-24 oz daily. This approach encourages the ingestion of foods richer in iron and prevents blood loss as a result of cow's milk–induced enteropathy.

When these preventive measures fail, routine screening helps prevent the development of severe anemia. Routine screening using hemoglobin or hematocrit is done at 12 mo of age, or earlier if at 4 mo of age the child is assessed to be at high risk for iron deficiency. Thereafter screening should continue if risk factors are identified.

Table 455-3 Differential Diagnosis of Microcytic Anemia That Fails to Respond to Oral Iron

- Poor compliance (true intolerance of Fe is uncommon)
- Incorrect dose or medication
- Malabsorption of administered iron
- Ongoing blood loss, including gastrointestinal, menstrual, and pulmonary
- Concurrent infection or inflammatory disorder inhibiting the response to iron
- Concurrent vitamin B_{12} or folate deficiency
- Diagnosis other than iron deficiency
  - Thalassemias
  - Hemoglobins C and E disorders
  - Anemia of chronic disease
  - Lead poisoning
  - Sickle thalassemias, hemoglobin SC disease
  - Iron refractory iron deficiency anemia (IRIDA)
  - Rare microcytic anemias (see Chapter 456)

Table 455-4 Responses to Iron Therapy in Iron-Deficiency Anemia

TIME AFTER IRON ADMINISTRATION	RESPONSE
12-24 hr	Replacement of intracellular iron enzymes; subjective improvement; decreased irritability; increased appetite
36-48 hr	Initial bone marrow response; erythroid hyperplasia
48-72 hr	Reticulocytosis, peaking at 5-7 days
4-30 days	Increase in hemoglobin level
1-3 mo	Repletion of stores

TREATMENT

The regular response of iron-deficiency anemia to adequate amounts of iron is a critical diagnostic and therapeutic feature (Table 455-4). Oral administration of simple ferrous salts (most often ferrous sulfate) provides inexpensive and effective therapy. There is no evidence that the addition of any trace metal, vitamin, or other hematinic substance significantly increases the response to simple ferrous salts. Aside from the unpleasant taste of iron, intolerance to oral iron is uncommon in young children. In contrast, older children and adolescents sometimes have GI complaints.

The therapeutic dose should be calculated in terms of elemental iron. A daily total dose of 3-6 mg/kg of elemental iron in 3 divided doses is adequate, with the higher dose used in more severe cases. The maximum dose would be 150-200 mg of elemental iron daily. Ferrous sulfate is 20% elemental iron by weight and is ideally given between meals with juice, although this timing is usually not critical with a therapeutic dose. Parenteral iron preparations are only used when malabsorption is present or when compliance is poor, because oral therapy is otherwise as fast, as effective, much less expensive and less toxic. When necessary, parenteral iron sucrose, ferric carboxymaltose, and ferric gluconate complex have a lower risk of serious reactions than iron dextran, although only the latter is FDA approved for use in children.

Iron therapy may increase the virulence of malaria and certain Gram-negative bacteria, particularly in developing countries. Iron overdose is associated with *Yersinia* infection.

In addition to iron therapy, dietary counseling is usually necessary. Excessive intake of milk, particularly cow's milk, should be limited. Iron deficiency in adolescent girls secondary to menorrhagia is treated with iron and menstrual control with hormone therapy (see Chapter 116.2).

If the anemia is mild, the only additional study is to repeat the blood count approximately 4 wk after initiating therapy. At this point, the hemoglobin has usually risen by at least 1-2 g/dL and has often normalized. If the anemia is more severe, earlier confirmation of the diagnosis can be made by the appearance of a reticulocytosis usually within 48-96 hr of instituting treatment. The hemoglobin will then begin to increase 0.1-0.4 g/dL per day depending on the severity of the anemia. Iron medication should be continued for 2-3 mo after blood values normalize to reestablish iron stores. Good follow-up is essential to ensure a response to therapy. When the anemia responds poorly or not at all to iron therapy, there are multiple considerations, including diagnoses other than iron deficiency (see Table 455-3).

Because a rapid hematologic response can be confidently predicted in typical iron deficiency, blood transfusion is rarely necessary. It should only be used when heart failure is imminent or if the anemia is severe with evidence of substantial ongoing blood loss. Unless there is active bleeding, transfusions must be given slowly to avoid precipitating or exacerbating congestive heart failure.

Chapter 456

Other Microcytic Anemias

Richard Sills

There are a number of rare microcytic anemias that need to be considered when children with microcytic anemia fail to respond to oral iron and more common diagnoses (see Chapter 462) are eliminated. In addition, although the anemia of chronic inflammation is usually normocytic, it can also be microcytic.

INFANTILE POIKILOCYTOSIS AND HEREDITARY PYROPOIKILOCYTOSIS

Infants with common hereditary elliptocytosis (see Chapter 459) may initially present with hemolytic anemia characterized by marked poikilocytosis with budding and fragmentation of the red blood cells. These small red blood cell fragments reduce the overall mean corpuscular volume, resulting in microcytosis. By 2 yr of age, the findings become typical of hereditary elliptocytosis. Hereditary pyropoikilocytosis is a much less common variant of hereditary elliptocytosis, in which the hemolytic anemia and red cell changes are more severe.

COPPER DEFICIENCY

Copper deficiency is a rare cause of microcytic anemia. It is associated with malabsorption, severe malnutrition often with feeding of milk alone, or parenteral nutrition with inadvertent omission of supplemental copper.

DEFECTS OF IRON METABOLISM

Rare microcytic anemias may be associated with defects in iron trafficking and regulation. Most are inherited and usually identified in childhood. They include defects of iron absorption, transport, utilization, and recycling. A *defect of iron absorption* is **iron refractory iron deficiency anemia**. This defect of transmembrane proteins causes a remarkably severe microcytosis out of proportion to the degree of anemia. This is an autosomal recessive disease due to loss of function mutations in *TMPRSS6*. In most cases, it is unresponsive to oral iron and partially responsive to intravenous iron. *Defects of iron recycling* include **aceruloplasminemia,** in which iron cannot be appropriately transported from macrophages to plasma.

Defects of mitochondrial iron utilization are a diverse group of acquired and inherited defects known as **sideroblastic anemias**. Impaired heme synthesis leads to retention of iron within the mitochondria of marrow red blood cells (RBCs). The perinuclear distribution of mitochondria results in a pattern of iron staining surrounding the nucleus. These are ringed sideroblasts (Fig. 456-1), which are distinct from the more diffuse cytoplasmic distribution of iron in normal RBC precursors. The anemia is characterized by hypochromic microcytic RBCs mixed with normal RBCs, so the complete blood cell count indicates a very high RBC distribution width. The serum iron concentration usually is elevated, and the transferrin saturation of iron is increased.

Congenital sideroblastic anemia is usually an X-linked disorder and is most commonly a result of mutations in erythrocytic isozyme 5-aminolevulinic acid synthetase, the rate-limiting enzyme reaction in heme synthesis. An important cofactor for 5-aminolevulinic acid synthetase is pyridoxal phosphate. Several of these mutations occur near the binding site for pyridoxal phosphate. Severe anemia is recognized in infancy or early childhood, whereas milder cases might not become apparent until early adulthood or later. **Clinical findings** include pallor, icterus, and moderate splenomegaly and/or hepatomegaly. The severity of the anemia varies such that some patients require no therapy and others need regular RBC transfusions. A subset of patients with hereditary sideroblastic anemia manifests a hematologic response to pharmacologic doses of pyridoxine. Iron overload as manifested by elevated serum ferritin, elevated serum iron, and increased transferrin saturation is a major complication of this disorder. Clinical evidence of iron overload (e.g., diabetes mellitus, liver dysfunction) may be found in some patients who have little or no anemia. Stem cell transplantation has been used to treat affected children who are dependent on RBC transfusions.

A unique variant of congenital sideroblastic anemia is **Pearson syndrome** (see Chapter 449), but the anemia is usually macrocytic and not microcytic. Another rare variant of sideroblastic anemia is due to mutations in *TRNT1* and manifests with developmental delay, recurrent fevers, and immunodeficiency in addition to anemia.

Acquired sideroblastic anemias can be triggered by drugs and toxins that disturb mitochondrial iron metabolism, including lead and isoniazid. The acquired neoplastic sideroblastic syndromes seen in adults are very rare in children.

Section 3

Hemolytic Anemias

Chapter 457

Definitions and Classification of Hemolytic Anemias

George B. Segel

Hemolysis is defined as the premature destruction of red blood cells (RBCs) (a shortened RBC life span). Anemia results when the rate of destruction exceeds the capacity of the marrow to produce RBCs. Normal RBC survival time is 110-120 days (half-life: 55-60 days), and thus, approximately 0.85% of the most senescent RBCs are removed and replaced each day. During hemolysis, RBC survival is shortened, the RBC count falls, erythropoietin is increased, and the stimulation of marrow activity results in heightened RBC production, reflected in an increased percentage of reticulocytes in the blood. Thus, hemolysis should be suspected as a cause of anemia if an elevated reticulocyte count is present. The reticulocyte count may also be elevated as a response to acute blood loss or for a short period after replacement therapy for iron, vitamin B_{12}, or folate deficiency. The marrow can increase its output 2-3–fold acutely, with a maximum of 6-8–fold in long-standing hemolysis. The reticulocyte percentage can be corrected to measure the magnitude of marrow production in response to hemolysis as follows:

$$\text{Reticulocyte index} = \text{reticulocyte\%} \times \frac{\text{Observed hematocrit}}{\text{Normal hematocrit}} \times \frac{1}{\mu}$$

where μ is a maturation factor of 1-3 related to the severity of the anemia (Fig. 457-1). The normal reticulocyte index is 1.0; therefore, the index measures the fold increase in erythropoiesis (e.g., 2-fold, 3-fold).

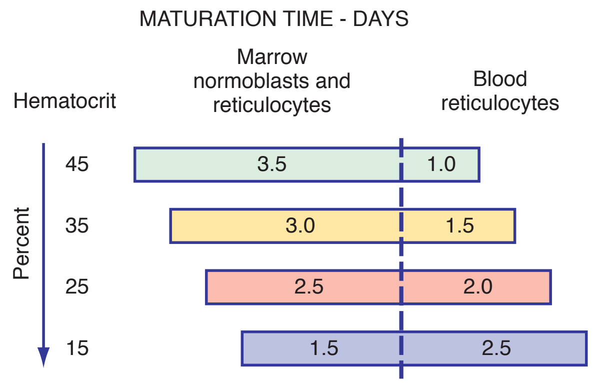

Figure 457-1 **Number of days for maturation of reticulocytes to mature erythrocytes in the marrow and blood.** The duration of maturation as blood reticulocytes is taken as μ, which is used in the correction equation in this chapter. *(Modified from Hillman RS, Finch CA:* Red cell manual, *Philadelphia, 1983, FA Davis.)*

As anemia becomes more severe, the erythropoietin concentration increases and reticulocytes are released from the marrow earlier; they are identifiable as reticulocytes in the blood that last for >1 day. Because the reticulocyte index is essentially a measure of RBC production per day, the maturation factor, μ, provides this correction (see Fig. 457-1).

The erythroid hyperplasia resulting from chronic hemolytic anemia in children, especially thalassemia, may be so extensive that the medullary spaces expand at the expense of the cortical bone. These changes may be evident on physical examination or on radiographs of the skull and long bones (see Fig. 462-7). A propensity to fracture long bones can also occur.

Direct assessment of the severity of hemolysis requires measurement of RBC survival time using RBCs tagged with the radioisotope $Na_2{}^{51}CrO_4$. The normal half-life of chromium 51–labeled RBCs is 25-35 days. This value is less than the expected half-life of 55-60 days because of the elution of chromium 51 from the labeled RBCs at the rate of approximately 1% day. Techniques to measure RBC survival using RBC biotin labeling do not require the use of isotopes.

The exaggerated degradation rate of hemoglobin results in increased biliary excretion of heme pigment derivatives and increased urinary and fecal urobilinogen (Fig. 457-2). Gallstones composed of calcium bilirubinate may be formed in children with chronic hemolysis as young as 4 yr of age. Elevations of serum unconjugated bilirubin and lactate dehydrogenase also can accompany hemolysis.

Three heme-binding proteins in the plasma are altered during hemolysis (see Fig. 457-2). Hemoglobin binds to haptoglobin and hemopexin, both of which are cleared more rapidly as conjugates, resulting in a reduced plasma concentration. Oxidized heme binds to albumin to form methemalbumin, which is increased in the plasma. When the capacity of these binding molecules is exceeded, free hemoglobin appears in the plasma, and the pink color can be seen if the plasma is partitioned after centrifugation in a capillary hematocrit tube. If present, free hemoglobin in the plasma is prima facie evidence of intravascular hemolysis. Free hemoglobin dissociates into dimers and is filtered by the kidneys. When the tubular reabsorptive capacity of the kidneys for hemoglobin is exceeded, free hemoglobin appears in the urine. Even in the absence of hemoglobinuria, iron loss can result from reabsorbed hemoglobin and the shedding of renal epithelial cells in which the iron from hemoglobin is stored as hemosiderin. This iron loss can lead to iron deficiency during chronic intravascular hemolysis. When hemoglobin is degraded, an α-methene bridge is broken in the cyclic tetrapyrrole of the heme moiety, with

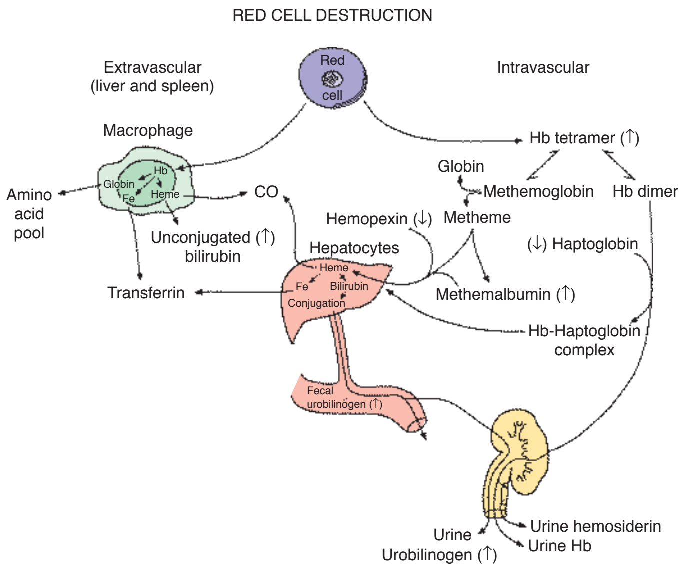

Figure 457-2 **Red cell destruction and catabolism of hemoglobin (Hb) based on the description by Hillman and Finch.** Fe, iron. *(From Hillman RS, Finch CA:* Red cell manual, *Philadelphia, 1983, FA Davis.)*

release of carbon monoxide (CO) (see Fig. 457-2). The amount of CO in the blood or expired air provides a dynamic measure of the hemolytic rate; end-tidal CO is not available in most clinical laboratories to measure hemolysis.

The hematocrit level depends on the severity of hemolysis and on the erythropoietic response. The shortened RBC life span and heightened RBC production result in a marked susceptibility to aplastic or hypoplastic crises, characterized by erythroid marrow failure and reticulocytopenia, accompanied by a rapid reduction in hemoglobin and hematocrit to extremely low levels. The most common cause of aplastic crisis is infection with parvovirus B19, which is erythrocytotropic (see Chapters 251 and 450). An aplastic crisis can produce a precipitous and life-threatening decline in hematocrit that usually lasts 10-14 days. Such transient erythroid marrow failure has only a mild effect in persons with a normal RBC life span, but it has a proportionately greater effect if the RBC life span is shortened by hemolysis. A second infection with parvovirus B19 is uncommon, but other infections can compromise erythroid marrow output, resulting in various degrees of hypoplasia or hypoplastic crises.

Hemolytic anemias may be classified as either cellular, resulting from intrinsic abnormalities of the membrane, enzymes, or hemoglobin; or extracellular, resulting from antibodies, mechanical factors, or plasma factors. Most cellular defects are inherited (paroxysmal nocturnal hemoglobinuria is acquired), and most extracellular defects are acquired (abetalipoproteinemia with acanthocytosis is inherited). Table 457-1 shows the most common hemolytic anemias, their underlying defects, the diagnostic laboratory tests, and recommendations for treatment.

Table 457-1 Hemolytic Anemias and Their Treatment

DIAGNOSIS	DEFECT	LABORATORY TESTS	TREATMENT
CELLULAR DEFECTS			
Membrane Defects			
Hereditary spherocytosis	Cytoskeletal protein defects Often involve vertical interactions of spectrin ankyrin, protein 3	Spherocytes on blood film Negative Coombs test eliminates immune hemolysis Increased incubated osmotic fragility Abnormal cytoskeletal protein analysis	If Hb >10 g/dL and reticulocyte count <10%: none If severe anemia, poor growth, aplastic crises, and age <2 yr: transfusion Folic acid, 1 mg qd Splenectomy (see text)
Hereditary elliptocytosis	Cytoskeletal protein defects Often involve horizontal interactions of spectrin, protein 4.1, and glycophorin c	Elliptocytes on blood film RBCs mildly heat-sensitive Abnormal cytoskeletal protein analysis	Mild types: no treatment Chronic hemolysis: transfusion and splenectomy as recommended for spherocytosis (see above) Folic acid, 1 mg qd
Hereditary pyropoikilocytosis	Cytoskeletal protein defects Homozygous or double heterozygous abnormality in horizontal interactions of α-spectrin	Extreme variation in RBC size and shape on blood film Thermal sensitivity-fragmentation at 45°C (113°F) for 15 min	Transfusion and splenectomy as recommended for spherocytosis (see above) Folic acid, 1 mg qd
Hereditary stomatocytosis	Cytoskeletal protein defects Decreased protein 7.2b (1 subset) Abnormal RBC cation and water content	Stomatocytes on blood film	Splenectomy should be avoided (see text) Folic acid, 1 mg qd
Paroxysmal nocturnal hemoglobinuria	Primary acquired marrow disorder RBCs unusually sensitive to complement-mediated lysis	Decreased WBC CD55 and CD59 or decreased RBC CD59 by flow cytometry Marrow aspirate and biopsy to assess cellularity Decreased decay-accelerating factor	Folic acid, 1 mg qd Mild cytopenias: no treatment Chronic hemolysis and other cytopenias: prednisone, qd initially, and then qod for maintenance therapy Iron for secondary iron deficiency Eculizumab (inhibits C5) Anticoagulation Marrow transplant for pancytopenia
Enzyme Deficiencies			
Pyruvate kinase deficiency	Decreased or abnormal enzyme	Pyruvate kinase assay: decreased V_{max} or, rarely, high K_m variant	In severe anemia with symptoms, poor growth and age <2 yr: transfusion Splenectomy age >6 yr, but earlier if necessary Folic acid, 1 mg qd
G6PD deficiency	A^- type: age-labile enzyme Mediterranean type: no enzyme activity in circulating RBCs	G6PD assay	Avoid oxidant stress to RBCs Transfusion if acute anemia is symptomatic
Hemoglobin Abnormalities			
For discussion of hemoglobinopathies, see sections on these topics.			

Table 457-1 Hemolytic Anemias and Their Treatment—cont'd

DIAGNOSIS	DEFECT	LABORATORY TESTS	TREATMENT
EXTRACELLULAR DEFECTS			
Autoimmune			
"Warm" antibody	Alteration in membrane surface antigen (Rh) or abnormal response of B lymphocytes, causing autoantibody formation "Molecular mimicry" to viral antigen	Spherocytes on blood film Positive direct antiglobulin (Coombs) test to IgG "warm" antibody or anti-C3d directed against RBCs Positive indirect Coombs test and antibody detectable in plasma Thermal amplitude 35-40°C (95-104°F) Some complement (C3b) may be detected on RBCs Tests for underlying disease	If Hb >10 g/dL and reticulocyte count <10%—none Severe anemia may require transfusion; prednisone, 2 mg/kg/24 hr IVIG ***Rituximab*** Splenectomy Immunosuppressives Folic acid, 1 mg/24 hr if chronic
"Cold" antibody	"Cold" or IgM autoantibody directed against I/i antigen system	Agglutination or rouleaux on blood film Positive direct Coombs test to complement (C3b) Tests for underlying disease Serology for infectious mononucleosis; anti-i present Serology for *Mycoplasma pneumoniae;* anti-I present	If Hb >10 g/dL and reticulocyte count <10%: none Severe anemia might require transfusion Avoid exposure to cold If severe: ***Rituximab*** Immunosuppressives and plasmapheresis Prednisone is less effective Splenectomy is not useful Folic acid, 1 mg/24 hr if chronic
Fragmentation Hemolysis			
DIC, TTP, HUS, aHUS, pneumococcal-induced HUS See Table 465-1	Direct damage to RBC membrane	Fragments on blood film	Treat underlying condition Transfusion, but transfused cells also will have shortened life span
Extracorporeal membrane oxygenation	Direct damage to RBC membrane	Fragments on blood film	Supportive Transfusion until ECMO is discontinued
Prosthetic heart valve	Direct damage to RBC membrane	Fragments on blood film	Folic acid, 1 mg/24 hr Iron for secondary iron deficiency
Burns, thermal injury	Direct damage to RBC membrane	Spherocytes on blood film	Supportive Transfusion
Hypersplenism	Effects of sequestration, ↓ pH, lipases and other enzymes, and macrophages on RBCs	Thrombocytopenia and neutropenia	Treat underlying condition: cytopenias all usually mild Splenectomy if complicating other anemia (e.g., thalassemia major) Folic acid, 1 mg/24 hr
Plasma Factors			
Liver disease	Alteration in plasma cholesterol and phospholipids	Target cells or spiculated RBCs on blood film Abnormal liver function tests	Treat underlying condition Transfusion, but transfused cells also will have shortened life span Folic acid, 1 mg/24 hr
Abetalipoproteinemia	Absence of apolipoprotein β Vitamin E deficiency and heightened sensitivity to oxidative damage	Acanthocytes on blood film Absent chylomicrons, VLDL, and LDL	Vitamin E (A, K, and D) Folic acid, 1 mg/24 hr Dietary restriction of triglycerides
Infections	Toxic effects on RBCs	Associated symptoms and signs Cultures	Antibiotics Supportive
Wilson disease	Effect of copper on RBC membrane, usually self-limited	Spherocytes on blood film Copper, ceruloplasmin Kaiser Fleischer rings Penicillamine challenge and urine copper excretion Liver biopsy for Cu content Gene analysis for mutation of ATP7B	Penicillamine Supportive Transfusion if acute anemia is symptomatic

aHUS, atypical hemolytic uremic syndrome; Cu, copper; DIC, disseminated intravascular coagulation; ECMO, extracorporeal membrane oxygenation; G6PD, glucose-6-phosphate dehydrogenase; Hb, hemoglobin; HUS, hemolytic uremic syndrome; Ig, immunoglobulin; IVIG, intravenous immunoglobulin; LDL, low-density lipoprotein; K_m, Michaelis constant; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura; VLDL, very-low-density lipoprotein; V_{max}, maximal velocity; WBC, white blood cell.

Chapter 458

Hereditary Spherocytosis

George B. Segel and Denise Casey

Hereditary spherocytosis (HS) is a common cause of hemolysis and hemolytic anemia, with a prevalence of approximately 1 in 5,000 persons. It is the most common inherited abnormality of the red blood cell (RBC) membrane. Although common among persons of Northern European origin, HS has been described in most ethnic groups. The more rare defects found in the United States and in Europe are the more common mutations described in the Japanese population. The clinical spectrum varies widely. Affected patients may be asymptomatic, without anemia and with minimal hemolysis, or they may have severe hemolytic anemia requiring regular blood transfusions and a splenectomy.

ETIOLOGY

Hereditary spherocytosis usually is transmitted as an autosomal dominant or, less commonly, as an autosomal recessive disorder. As many as 25% of patients have no previous family history. Of these patients, most represent new mutations, and a few cases result from recessive inheritance or represent nonpaternity. The pathophysiology underlying HS involves 5 proteins, which are key components of the cytoskeleton responsible for RBC shape (Table 458-1). Abnormalities of spectrin or ankyrin are the most common molecular defects. Dominant defects have been described in β-spectrin and band 3. Recessive defects have been described in α-spectrin and protein 4.2. Both dominant and recessive defects have been described in ankyrin (Table 458-1). A deficiency in spectrin, band 3, ankyrin, or protein 4.2 results in uncoupling in the "vertical" interactions of the lipid bilayer skeleton and subsequent release of membrane microvesicles. The loss of membrane surface area without a proportional loss of cell volume causes sphering of the RBCs, and an associated increase in cation permeability, cation transport, adenosine triphosphate use, and glycolysis. The decreased deformability of the spherocytic RBCs impairs cell passage from the splenic cords to the splenic sinuses, and the spherocytic RBCs are destroyed prematurely in the spleen (Figs. 458-1 and 458-2). Splenectomy markedly improves RBC life span and may be indicated in some patients with HS.

CLINICAL MANIFESTATIONS

In the neonatal period, HS is a significant cause of hemolytic disease and can be manifest as anemia and hyperbilirubinemia sufficiently severe to require phototherapy or exchange transfusions. Hemolysis may be more prominent in the newborn because hemoglobin F binds 2,3-diphosphoglycerate poorly, and the increased level of free 2,3-diphosphoglycerate destabilizes interactions among spectrin, actin, and protein 4.1 in the RBC membrane (see Fig. 458-1). The need for exchange transfusion at birth or transfusions in infancy is not indicative of more severe disease later in life because infants do not mount an adequate reticulocyte response until several months after birth.

Some patients remain asymptomatic into adulthood, but others have severe anemia with pallor, jaundice, fatigue, and exercise intolerance. Severe cases may be marked by expansion of the diploë of the skull as a result of marrow hyperplasia (frontal bossing), but to a lesser extent than in thalassemia major. Depending on the severity of the anemia and the comorbidities associated with severe anemia, some patients benefit from a splenectomy (Table 458-2).

After infancy, splenomegaly is common; there is no correlation between spleen size and disease severity. Bilirubin gallstone formation is a function of age; they can form as early as age 4-5 yr and are present in the majority of adult patients.

Children with HS are also susceptible to aplastic crises, primarily as a result of parvovirus B19 infection, and to hypoplastic crises associated with various other infections (Fig. 458-3). High RBC turnover in the setting of erythroid marrow failure can result in profound anemia (hematocrit <10%), high-output heart failure, cardiovascular collapse, and death. White blood cell and platelet counts can also fall (Fig. 458-3). Rare complications associated with HS include splenic sequestration crisis, gout, cardiomyopathy, priapism, leg ulcers, and spinocerebellar degeneration.

DIAGNOSIS

Evidence of hemolysis includes reticulocytosis and indirect hyperbilirubinemia. The hemoglobin level usually is 6-10 g/dL, but it can be in the normal range. The reticulocyte percentage often is increased to 6-20%, with a mean of approximately 10%. The mean corpuscular

volume is normal, although the mean corpuscular hemoglobin concentration often is increased (36-38 g/dL RBCs). The RBCs on the blood smear vary in size and include polychromatophilic reticulocytes and spherocytes (Fig. 458-4). The spherocytes are smaller in diameter and appear hyperchromic as a result of the high hemoglobin concentration. The central pallor is less conspicuous than in normal cells. Spherocytes may be the predominant cells or may be relatively sparse, depending on the severity of the disease, but they usually account for >15% of the cells when hemolytic anemia is present. Other evidence of hemolysis includes decreased haptoglobin and the presence of gallstones on ultrasonography.

The diagnosis of HS can be established from a positive family history and the presence of typical clinical and laboratory features of the disease: splenomegaly, spherocytes on the blood smear, reticulocytosis, and an elevated mean corpuscular hemoglobin concentration. If these are present, no additional testing is necessary to confirm the diagnosis. If the diagnosis is less certain, the recommended tests that have a high predictive value for HS are the flow cytometric EMA (eosin-5-maleimide) binding test and the cryohemolysis test. Although no test for HS is 100% reliable, the EMA binding test had a diagnostic sensitivity and specificity of 93% and 98%, respectively, in a recent large study. Other assays, such as the acidified glycerol lysis test and osmotic gradient ektacytometry, also have increased sensitivity for HS. The classic incubated osmotic fragility test can detect the presence of spherocytes in the blood; however, it is not specific to HS and may be abnormal in other hemolytic anemias. The RBCs are incubated in progressive dilutions of sodium chloride causing the RBCs to swell and eventually lyse. Spherocytes lyse at a higher sodium chloride concentration than biconcave cells in hypotonic solutions because they have a lower surface area : volume ratio. Unfortunately, this test has poor sensitivity relative to other screening assays and can miss up to 20% of mild HS cases.

As a research tool and for atypical cases, the specific membrane abnormality can be established by gel electrophoresis analysis of RBC membrane proteins. Molecular diagnosis also is possible because most patients having a family-specific private mutation can be detected by DNA analysis.

DIFFERENTIAL DIAGNOSIS

The major alternative considerations when large numbers of spherocytes are seen on the blood smear are isoimmune and autoimmune hemolysis. Isoimmune hemolytic disease of the newborn, particularly when a result of ABO incompatibility, mimics the cell appearance of HS. The detection of antibody on an infant's RBCs using a direct antiglobulin (Coombs) test should establish the diagnosis of immune hemolysis. Autoimmune hemolytic anemias also are characterized by spherocytes; however, there may be evidence of previously normal values for hemoglobin, hematocrit, and reticulocyte count. Rare causes of spherocytosis include thermal injury, clostridial septicemia, and Wilson disease, each of which can manifest as transient hemolytic anemia (see Table 457-1 in Chapter 457).

TREATMENT

General Supportive Care

Parents should be advised of the risk of newborn jaundice and the potential need for phototherapy and exchange transfusion after birth to decrease bilirubin levels. Infants born to parents with known HS should be monitored carefully as hyperbilirubinemia may peak several days after birth. A minority of infants will be transfusion-dependent

until development of adequate erythropoiesis to compensate for the ongoing hemolysis. Continued transfusion-dependence is not common after 6-12 mo of age.

Once the baseline level of disease severity is reached, an annual visit to the hematologist usually is sufficient. Growth should be monitored, exercise tolerance and spleen size documented, and parents should receive anticipatory guidance regarding the risk of aplastic crisis secondary to parvovirus, and hypoplastic crises with other infections. Parents and patients should be informed of an increased risk for gallstone development. The degree of splenomegaly does not correlate with disease severity. Folic acid supplementation is recommended in moderate and severe HS because of an enhanced requirement with increased erythropoiesis.

Guidelines for Splenectomy

Because the spherocytes are destroyed almost exclusively in the spleen, splenectomy eliminates most of the hemolysis. After splenectomy, the anemia, hyperbilirubinemia, and incidence of gallstones are significantly lessened, if not completely eradicated. However, splenectomy is associated with immediate surgical morbidities in addition to a lifelong increased risk for sepsis, particularly that caused by pneumococcal species. This risk is not completely eliminated with the requisite preoperative and postoperative vaccination against pneumococcus, meningococcus, and *Haemophilus influenzae type b*.

Splenectomy is recommended for patients with severe HS. It should be considered for patients with moderate HS and frequent hypoplastic or aplastic crises, poor growth, or cardiomegaly. It is generally not recommended for patients with mild HS. When splenectomy is indicated, it should be performed after the age of 6 yr, if possible, to avoid the heightened risk of postsplenectomy sepsis in younger children. The laparoscopic approach has less surgical morbidity and is recommended if the surgeon is adequately trained in this approach. Partial splenectomy may be beneficial but needs further study. In children undergoing splenectomy, a concomitant cholecystectomy should be performed if there are gallstones. It is controversial whether to perform a concomitant splenectomy in less-severely ill patients who are undergoing cholecystectomy for gallstone disease. Postsplenectomy thrombocytosis is commonly observed, but requires no treatment and usually resolves spontaneously. Vaccines for encapsulated organisms, such as pneumococcus, meningococcus, and *H. influenzae type b*, should be administered at least 14 days before splenectomy, and prophylactic oral penicillin VK prescribed indefinitely.

Chapter 459
Hereditary Elliptocytosis

George B. Segel

Hereditary elliptocytosis is a less common disorder than spherocytosis and also varies markedly in severity. Mild hereditary elliptocytosis produces no symptoms; more severe varieties can result in neonatal poikilocytosis (shape variation) and hemolysis, chronic or sporadic hemolytic anemia, or **hereditary pyropoikilocytosis (HPP)**, which is a severe disorder with microspherocytosis and poikilocytosis. Hereditary elliptocytosis is rare in Western populations and is more common among West Africans.

ETIOLOGY

Hereditary elliptocytosis is inherited as a dominant disorder. In the rare instances, when 2 abnormal alleles are inherited (HPP), the patient exhibits particularly severe hemolytic anemia. Various molecular defects have been described in hereditary elliptocytosis; these produce abnormalities of α- and β-spectrin and defective spectrin heterodimer self-association (see Fig. 458-1). The abnormalities (spectrin mutations) can provide resistance to malarial infection. Such defects in horizontal protein interactions result in gross membrane fragmentation, particularly in homozygous HPP. Less commonly, mutations in protein 4.1 and glycophorin C can produce elliptocytosis.

CLINICAL MANIFESTATIONS

Elliptocytosis may be an incidental finding on a blood film examination and might not be associated with clinically significant hemolysis (see Fig. 458-4*B*). The diagnosis of hereditary elliptocytosis is established by the findings on the blood film, the autosomal dominant inheritance pattern, and the absence of other causes of elliptocytosis, such as deficiencies of iron, folic acid, or vitamin B_{12}. Hemolytic elliptocytosis can produce neonatal jaundice, even though characteristic elliptocytosis might not be evident at that time. The blood of the affected newborn can show bizarre poikilocytes and pyknocytes. Transient augmented fragmentation and hemolysis in the newborn can result from the presence of hemoglobin F that binds poorly to the glycolytic intermediate 2,3-diphosphoglycerate. The increased 2,3-diphosphoglycerate tends to destabilize the spectrin–actin–protein 4.1 complex, leading to membrane instability (see Fig. 458-1).

The usual features of a chronic hemolytic process with elliptocytosis are manifested later as anemia, jaundice, splenomegaly, and osseous changes. Cholelithiasis can occur in later childhood; aplastic crises have been reported. The most severe form is HPP, which is characterized by extreme microcytosis (mean corpuscular volume, 50-60 fL/cell), extraordinary variation in cell size and shape, and primarily microspherocytic rather than elliptocytic cells (see Fig. 458-4*C*). The red blood cells (RBCs) have heightened sensitivity to heat, hence the "pyro" designation. These patients usually inherit a mutant spectrin from one parent, who has mild or no elliptocytosis (silent carrier), and a partial spectrin deficiency from the other parent, who is hematologically normal.

Ovalocytes, in contrast to elliptocytes, are less elongated and might reflect a condition known as *Southeast Asian ovalocytosis* (SAO). SAO is associated with an abnormal protein 3, which functions as an anion exchanger. This disorder can produce neonatal hyperbilirubinemia, but it causes little hemolysis later. It might offer protection against *Plasmodium falciparum* malaria because normal protein 3 is one of the malarial receptors. Protein 3 as an anion exchanger is also expressed in renal tubular cells and can cause distal renal tubular acidosis in association with SAO.

LABORATORY FINDINGS

The blood film is the most important test to establish hereditary elliptocytosis (see Fig. 458-4*B*). The RBCs show various degrees of elongation and can actually be rod shaped. In hereditary elliptocytosis, other abnormal RBC shapes may be present, depending on the severity of hemolysis. They include microcytes, spherocytes, and other poikilocytes. The increase in the reticulocyte percentage reflects the severity of hemolysis; erythroid hyperplasia and indirect hyperbilirubinemia may be present. Increased thermal instability is characteristic of HPP. The abnormal spectrin denatures and the cells lyse at 45-46°C (113-114.8°F) instead of the usual 49-50°C (120.2-122°F). The specific protein abnormality can be established by protein separation and analysis techniques. The eosin-5-maleimide binding test, which detects binding to protein band 3 by flow cytometry, may be useful in conjunction with the mean corpuscular volume in diagnosing hereditary elliptocytosis and hereditary spherocytosis. Molecular defects are defined only in research laboratories.

TREATMENT

If hereditary elliptocytosis represents a morphologic abnormality on the blood film without evident hemolysis, no treatment is necessary. Patients with chronic hemolysis should receive folic acid, 1 mg daily, to prevent secondary folic acid deficiency. Splenectomy decreases the

hemolysis and should be considered if the hemoglobin is <10 g/dL and the reticulocyte count is >10%. The RBCs on the blood film may be more abnormal after splenectomy, even though hemoglobin increases and reticulocytes decrease. The hematologic features of SAO do not require treatment beyond the newborn period.

Chapter 460
Hereditary Stomatocytosis

George B. Segel and Lisa R. Hackney

Hereditary stomatocytosis includes a rare group of dominantly inherited hemolytic anemias in which there are characteristic morphologic changes in the red blood cells (RBCs) and increased red cell cation permeability. The RBCs are cup-shaped, creating a mouth-shaped area (stoma) of central pallor instead of the usual circular area of central pallor. Hereditary stomatocytosis is classified by the RBC hydration status. The 2 major varieties are either overhydrated (hydrocytosis) or dehydrated (xerocytosis).

HYDROCYTOSIS
Pathophysiology
Stomatocytes of the hydrocytic variant have excess intracellular sodium and water content and decreased intracellular potassium content. The principal defect in this variant is an increase in Na^+ and K^+ permeability, caused by mutations in rhesus-associated glycoproteins. However, the amount of Na^+ influx exceeds the K^+ efflux, and the cells subsequently develop increased cation content and water, and thus swell. These hydrocytic cells have increased osmotic fragility. Additionally, the integral membrane protein, stomatin or band 7.2 b, is decreased or absent from the erythrocyte membrane. The function of stomatin is not fully understood, although it might act as a switch that influences the function of GLUT1, the glucose transporter. It has been found that stomatin in the hydrocytic variant is synthesized early in RBC development but is lost as the cell matures. The mechanism for this loss of stomatin is not yet determined. It also is unclear how the loss of stomatin expression contributes to the cation leak, which is characteristic of this variant.

Clinical Features
The hydrocytic variant is the most severe form of hereditary stomatocytosis and is characterized by moderate to severe hemolysis, macrocytosis, and large numbers of stomatocytes on the blood smear. Patients commonly develop jaundice, splenomegaly, and cholelithiasis.

XEROCYTOSIS
Pathophysiology
The xerocytic variant is the more common form of hereditary stomatocytosis and usually results in a milder anemia in affected patients. The underlying cation defect is a net loss of RBC potassium that is not accompanied by an increase in sodium. Subsequently, the erythrocyte develops decreased intracellular water content and becomes dehydrated. It may be associated with a syndrome of perinatal edema and ascites. These findings are transient and remain unexplained.

Clinical Features
Patients affected by the xerocytic variant have a mild compensated macrocytic hemolytic anemia, variable numbers of stomatocytes and/or target cells on peripheral smear, increased mean corpuscular hemoglobin concentration as a result of the cellular dehydration, and, typically, jaundice and splenomegaly.

INTERMEDIATE SYNDROMES
The **Rh deficiency syndrome** is characterized by an absence or profound decrease in the Rh antigen on the RBC membrane. Affected RBCs in this disorder are dehydrated and have decreased cell cation and water content. This decreased cell cation content may be the result of increased potassium leak in spite of increased Na^+-K^+ pump activity. This syndrome is associated with mild to moderate hemolytic anemia, reticulocytosis, and stomatocytes and spherocytes on the blood smear.

Cryohydrocytosis is a mild form of stomatocytosis, typically caused by mutations in *SLC4A1* coding for the band 3 anion exchanger, in which the RBCs lyse on cooling in vitro and may be associated with "pseudohyperkalemia."

Absence of high-density lipoproteins (an **α-lipoproteinemia** or **Tangier disease**) can lead to hematologic manifestations such as a moderate hemolytic anemia, stomatocytosis, and thrombocytopenia. Affected patients can also have large orange tonsils, hepatosplenomegaly, lymphadenopathy, cloudy corneas, and peripheral neuropathy.

One of the most flagrant forms of stomatocytosis is seen in **phytosterolemia**, another metabolic disorder, in which the absorption of sterols, both cholesterol and its plant-derived relatives (e.g., sitosterol), is unlimited and unselective. The cells are not leaky to cations; there is macrothrombocytopenia and a degree of short stature. The plasma cholesterol may or may not be abnormal, but mass spectrography always shows a massive increase in plant sterol levels.

OTHER DISORDERS ASSOCIATED WITH STOMATOCYTOSIS
Acquired stomatocytosis may be seen with liver disease but also in alcoholism, malignancy, and cardiovascular disease. Stomatocytes can be seen on the blood smears of normal patients as a result of drying artifact.

TREATMENT
For severe hemolysis, patients might require RBC transfusion. Splenectomy is not recommended as a treatment for cation-leaky hereditary stomatocytosis. It is not effective and predisposes patients to in situ thrombosis after splenectomy. The thrombosis appears related to abnormal adherence of stomatocytic erythrocytes to the vascular endothelium.

Chapter 461

Paroxysmal Nocturnal Hemoglobinuria and Acanthocytosis

George B. Segel

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Etiology

Paroxysmal nocturnal hemoglobinuria (PNH) reflects an abnormality of marrow stem cells that affects each blood cell lineage. The disease is

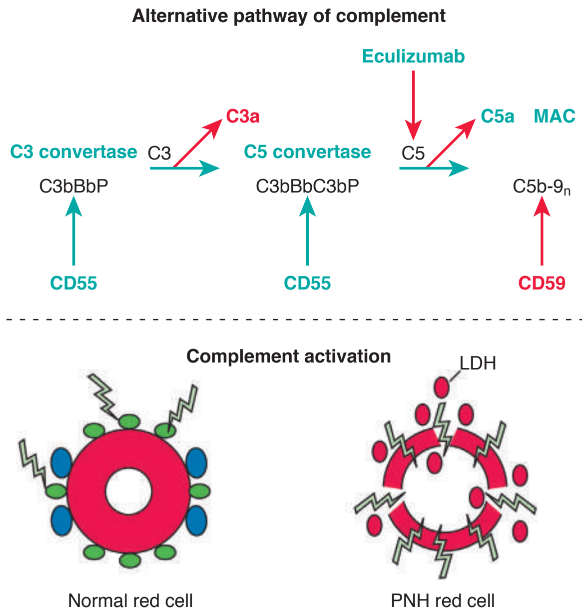

Figure 461-1 Complement-mediated lysis in PNH. Red circles are hemoglobin. Blue circles are decay accelerating factor (CD55). Green circles are membrane inhibitor of reactive lysis (CD59). Bb, activated factor B; C3b, activated C3; C5b, activated C5; GPI, glycosyl phosphatidylinositol; MAC, membrane attack complex (consisting of C5b, C6, C7, C8, and several molecules of C9 [9n]); RBC, red blood cell. *(From Parker C: Eculizumab for paroxysmal nocturnal haemoglobinuria,* Lancet *373:759–767, 2009.)*

an acquired somatic mutation that results in a defect in proteins of the cell membrane that renders the red blood cells (RBCs) and other cells susceptible to damage by normal plasma complement proteins (Fig. 461-1). The deficient membrane-associated proteins include decay-accelerating factor (CD55), the membrane inhibitor of reactive lysis (CD59), the C8 binding protein, and other proteins that normally impede complement lysis at various steps, specifically, the alternative pathway, which is constitutively activated. The underlying defect involves the glycolipid anchor that maintains these protective proteins on the cell surface. Various mutations in the *PIGA* gene that is involved in glycosylphosphatidylinositol anchor protein biosynthesis have been identified in patients with PNH. Glycosylphosphatidylinositol-deficient cells are found at low frequency in normal persons, suggesting that injury to the normal marrow stem cells provides a selective advantage to the progeny of PNH clones in the genesis of this disease.

Clinical Manifestations

PNH is a rare disorder in children. Approximately 60% of pediatric patients have marrow failure, and the remainder have either intermittent or chronic anemia, often with prominent intravascular hemolysis. Nocturnal and morning hemoglobinuria is a classic finding in adults when hemolysis is worse during sleep; chronic hemolysis is more common. In addition to chronic hemolysis, thrombocytopenia and leukopenia are often characteristic. Hemoglobinuria is rarely seen in children compared to adults with PNH. *Thrombosis and thromboembolic phenomena* are serious complications that may be related to altered glycoproteins on the platelet surface and resultant platelet activation and production of procoagulant microparticles. Abdominal venous thrombosis presents as recurrent episodes of abdominal pain, Budd-Chiari syndrome (hepatic veins), or splenomegaly (splenic vein). Furthermore, released free hemoglobin results in depletion of nitric oxide, fostering vasoconstriction, thrombosis, and pain. Back and head pain may also be prominent. Hypoplastic or aplastic pancytopenia can precede or follow the diagnosis of PNH; rarely, PNH may progress to acute myelogenous leukemia. At the time of presentation, more than 90% of patients with PNH have some blood abnormality (including ~35% with anemia alone, ~15% with anemia and thrombocytopenia, ~7% with anemia and neutropenia, and ~30% with pancytopenia), >10% have abdominal pain, and >5% have thrombosis. The mortality in PNH is related primarily to the development of aplastic anemia or thrombotic complications. The predicted survival rate for children before the development of eculizumab (see Treatment below) was 80% at 5 yr, 60% at 10 yr, and 28% at 20 yr.

Laboratory Findings

Hemosiderinuria, an elevated reticulocyte percentage, a low serum haptoglobin, and increased lactic dehydrogenase are common and reflect chronic intravascular hemolysis. Initially, the anemia is normocytic, but if iron deficiency develops, it becomes microcytic. Markedly reduced levels of RBC acetylcholinesterase activity and decay-accelerating factor also are found. Flow cytometry is the diagnostic test of choice for PNH. With the use of anti-CD59 for RBCs and anti-CD55 and anti-CD59 for granulocytes, flow cytometry is more sensitive than the classic RBC lysis (ham or sucrose) tests in detecting these reduced glycolipid-bound membrane proteins. Fluorescent-labeled aerolysin testing can heighten the sensitivity of detection by binding selectively to glycosylphosphatidylinositol anchors.

Treatment

Glucocorticoids such as prednisone (2 mg/kg/24 hr) have been used to treat acute hemolytic episodes; the dosage should be tapered as soon as the hemolysis abates. Prolonged anticoagulation (heparin or low-molecular-weight heparin) therapy may be of benefit when thromboses occur. Because of chronic urinary loss of iron as hemosiderin, iron therapy may be necessary. Androgens (e.g., fluoxymesterone [Halotestin]), antithymocyte globulin, cyclosporine, and growth factors (e.g., erythropoietin and granulocyte colony-stimulating factor) have been used to treat marrow failure. Bone marrow transplantation is successful in treating some cases; nonmyeloablative transplantation can reduce transplant-related mortality and morbidity.

Marrow failure and severe thrombosis are the most serious complications in children. Treatment has included hematopoietic stem cell transplantation if a suitable donor exists. Eculizumab has also resulted in sustained survival in the majority of patients. Eculizumab is an approved and effective treatment for PNH in adults. It is a monoclonal antibody against complement component C5, and it interrupts the excessive complement destruction of RBC and activation of platelets. It decreases the rate of hemolysis, stabilizes hemoglobin levels, reduces the number of transfusions, and reduces the risk of thrombosis. Survival in adults with PNH treated with eculizumab may not be different from sex- and age-matched control patients from the general population. However, the medication does not improve the hematopoietic clonal expansion or prevent marrow failure. Because of the cost and length of treatment required, particularly in children, it may be most useful in preventing thrombosis, anemia, and other symptoms while stem cell transplant is considered. Before beginning eculizumab, it is recommended to immunize patients with the meningococcal vaccine if the patient hasn't already received this vaccine. A poor response to eculizumab may be due to polymorphisms in the C5 gene that produce resistance to eculizumab blockades.

ACANTHOCYTOSIS

Acanthocytosis is characterized by RBCs with irregular circumferential pointed projections (see Fig. 458-4*E*). This morphologic finding is seen with alterations in the cholesterol : phospholipid ratio in some patients with liver disease or vitamin E deficiency, and in congenital abetalipoproteinemia or hypoprebetalipoproteinemia, associated with fat malabsorption, neuromuscular abnormalities, and retinitis pigmentosa (see Chapters 86.3 and 630). Normoproteinemic **neuroacanthocytosis** is also associated with 4 genetically diverse conditions (Table 461-1). These include chorea-acanthocytosis and the rare X-linked McLeod syndrome, which has absence of the KX (Kell) antigen, late-onset myopathy, peripheral neuropathy, chorea, splenomegaly, and hemolysis with acanthocytosis. There is usually >3% acanthocytes on peripheral smear and caudate atrophy noted on MRI. Acanthocytes

Table 461-1 Neuroacanthocytosis		
DISEASE	**INHERITANCE**	**MUTATION**
Chorea acanthocytosis	Autosomal recessive	VPS13A (*CHAC* gene)
McLeod syndrome	X-linked recessive	*XK* gene
Huntington disease–like 2	Autosomal dominant	JPH3
Pantothenate kinase-associated neurodegeneration	Autosomal recessive	PANK2

also are seen in pantothenate kinase-associated neurodegeneration (dystonia, rigidity, chorea, dysarthria, spasticity, retinopathy) and Huntington disease–like 2. The production of acanthocytes in chorea-acanthocytosis appears related to altered Lyn kinase activity with increased tyrosine phosphorylation and altered linkage of band 3 to other RBC membrane proteins.

In contrast, echinocytes or "burr cells" have a more regular distribution of projections or serrations along the surface of the RBCs. They often are seen as artifact, and less often in end-stage renal disease, and in some patients with liver disease.

Chapter 462 Hemoglobinopathies

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

HEMOGLOBIN DISORDERS

Hemoglobin is a tetramer consisting of 2 pairs of globin chains. Abnormalities in these proteins are referred to as *hemoglobinopathies.*

More than 800 variant hemoglobins have been described. The most common and useful clinical classification of hemoglobinopathies is based on nomenclature associated with alteration of the involved globin chain. Two hemoglobin gene clusters are involved in the production of hemoglobin and are located at the end of the short arms of chromosomes 16 and 11. Their control is complex, including an upstream locus control region on each respective chromosome and an X-linked control site. On chromosome 16, there are 3 genes within the alpha (α) gene cluster, namely zeta (ζ), alpha 1 (α_1), and alpha 2 (α_2). On chromosome 11, there are 5 genes within the beta (β) gene cluster, namely epsilon (ε), 2 gamma genes (γ), a delta gene (δ), and a beta gene (β).

The order of gene expression within each cluster roughly follows the order of expression during the embryonic period, fetal period, and eventually childhood. After 8 wk of fetal life, the embryonic hemoglobins, Gower-1 ($\zeta_2\varepsilon_2$), Gower-2 ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$), are formed. At 9 wk of fetal life, the major hemoglobin (Hb) is HbF ($\alpha_2\gamma_2$). HbA ($\alpha_2\beta_2$) first appears at approximately 1 mo of fetal life, but does not become the dominant hemoglobin until after birth, when HbF levels start to decline. HbA_2 ($\alpha_2\delta_2$) is a minor hemoglobin that appears shortly before birth and remains at a low level after birth. The final hemoglobin distribution pattern that occurs in childhood is not achieved until at least 6 mo of age and sometimes later. The normal hemoglobin pattern is ≥95% HbA, ≤3.5 HbA_2, and <2.5% HbF.

462.1 Sickle Cell Disease

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

Great strides have been made in the management of both acute and chronic complications of sickle cell disease with a significant improvement in the life expectancy of a child born today in the United States. However, the majority of children with sickle cell disease are born outside of the United States with limited access to preventive care and disease-modifying treatments.

Children with sickle cell disease should be followed by experts in the management of this disease, most often by pediatric hematologists. Medical care provided by a pediatric hematologist is also associated with a decreased frequency of emergency department visits and length of hospitalization when compared to patients who were not seen by a hematologist within the last year.

PATHOPHYSIOLOGY

Hemoglobin S (HbS) is the result of a single base-pair change, thymine for adenine, at the sixth codon of the β-globin gene. This change encodes valine instead of glutamine in the 6th position in the β-globin molecule. Sickle cell anemia (HbSS), homozygous HbSS, occurs when both β-globin alleles have the sickle cell mutation (βs). Sickle cell disease refers to not only patients with sickle cell anemia, but also to compound heterozygotes where one β-globin allele includes the sickle cell mutation and the second β-globin allele includes a gene mutation other than the sickle cell mutation, such as HbC, β-thalassemia, HbD, and HbO^{Arab}. In sickle cell anemia, HbS is commonly as high as 90% of the total hemoglobin; whereas as in sickle cell disease, HbS is >50% of all hemoglobin.

In red blood cells, the hemoglobin molecule has a highly-specified conformation allowing for the transport of oxygen in the body. In the absence of globin-chain mutations, hemoglobin molecules do not interact with one another. However, the presence of HbS results in a conformational change in the hemoglobin tetramer and, in the deoxygenated state, HbS molecules can now interact with each other forming rigid polymers that give the red blood cell its characteristic "sickled" shape. The lung is the only organ capable of reversing the polymers, and any disease of the lung can be expected to compromise the degree of reversibility.

Intravascular sickling primarily occurs in the postcapillary venules and is a function of both mechanical obstruction by sickled red blood cells and increased adhesion between red blood cells, leukocytes and the vascular endothelium. Sickle cell disease is also an inflammatory disease based on nonspecific markers of inflammation, including, but not limited to, elevated baseline white blood cell count and cytokines.

DIAGNOSIS AND EPIDEMIOLOGY

Every state in the United States has instituted a mandatory newborn screening program for sickle cell disease. Such programs identify newborns with the disease and provide prompt diagnosis and referral to providers with expertise in sickle cell disease for anticipatory guidance and the initiation of penicillin before 4 mo of age.

The most commonly used procedures for newborn diagnosis include thin layer/isoelectric focusing and high-performance liquid chromatography (HPLC). A confirmatory step is recommended, with all patients who have initial abnormal screens being retested during the first clinical visit and after 6 mo of age to determine the final hemoglobin phenotype. In addition, a complete blood cell count (CBC) and hemoglobin phenotype determination is recommended for both parents to confirm the diagnosis and to provide an opportunity for genetic counseling. Table 462-1 correlates the initial hemoglobin phenotype at birth with the type of hemoglobinopathy, baseline hemoglobin range, and requirement for a hematologist.

In newborn screening programs, the hemoglobin with the greatest quantity is reported first, followed by other hemoglobins in order of decreasing quantity. In newborns with a hemoglobin analysis result

Table 462-1 Various Newborn Sickle Cell Disease Screening Results with Baseline Hemoglobin

NEWBORN SCREENING RESULTS: SICKLE CELL DISEASE*	POSSIBLE HEMOGLOBIN PHENOTYPE†	BASELINE HEMOGLOBIN RANGE	EXPERTISE IN HEMATOLOGY CARE REQUIRED
FS	SCD-SS SCD-S β^0 thal SCD-S β^+ thal SCD-S $\delta\beta^-$ thal S HPFH	6-11 g/dL 6-10 g/dL 9-12 g/dL 10-12 g/dL 12-14 g/dL	Yes Yes Yes Yes Yes
FSC	SCD-SC	10-15 g/dL	Yes
FSA	SCD-S β^+ thal	9-12 g/dL	Yes
FS other	SCD-S β^0 thal SCD-SD, SO^{Arab}, SC^{Harlem}, S^{Lepore}	6-10 g/dL Variable	Yes Yes
AFS	SCD-SS SCD-S β^+ thal SCD-S β^0 thal‡	6-10 g/dL 6-9 g/dL 7-13 g/dL variable	Yes Yes Yes

*Hemoglobins are reported in order of quantity.

†Requires confirmatory hemoglobin analysis after at least 6 mo of age and, if possible, hemoglobin analysis from both parents for accurate diagnosis of hemoglobin phenotype.

‡Impossible to determine the diagnosis because the infant received a blood transfusion before testing.

A, normal hemoglobin; C, hemoglobin C; F, fetal hemoglobin; HPFH, hereditary persistence of fetal hemoglobin; O^{Arab}, hemoglobin O^{Arab}; S, sickle hemoglobin; SC, sickle-hemoglobin C; SCD, sickle cell disease; SS, homozygous sickle cell disease; thal, thalassemia.

of FS, the pattern supports HbSS, HbS hereditary persistent fetal hemoglobin (HPFH), or HbSβ-thalassemia zero. In a newborn with a hemoglobin analysis of FSA, the pattern is supportive of diagnosis HbSβ-thalassemia+. The diagnosis of HbSβ-thalassemia+ is confirmed if at least 50% of the hemoglobin is HbS, HbA is present, and the amount of HbA_2 is elevated (typically >3.5%); although, HbA_2 is not elevated in the newborn period. In newborns with a hemoglobin analysis of FSC, the pattern supports a diagnosis of HbSC. In newborns with a hemoglobin analysis of FAS, the pattern supports a diagnosis of HbAS (sickle cell trait).

A newborn with a hemoglobin analysis of AFS has been transfused with red blood cells prior to collection of the newborn screen because the amount of HbA is greater than the amount of HbF or there has been an error. The patient may have either sickle cell disease or sickle cell trait and should be started on penicillin prophylaxis until the final diagnosis can be determined.

Given the implications of a diagnosis of sickle cell disease versus sickle cell trait in a newborn, repeating the hemoglobin analysis in the patient and obtaining a hemoglobin analysis and CBC to evaluate the smear and red blood cell parameters in the parents for genetic counseling cannot be overemphasized. Unintended mistakes do occur in state newborn screening programs. Newborns who have the initial phenotype of HbFS but whose final true phenotype included HbSβ-thalassemia+ have been described as one of the more common errors identified in newborn screening hemoglobinopathy programs. Determining an accurate phenotype is important for appropriate genetic counseling for the parents.

In the event that the parents are tested for sickle cell trait or hemoglobinopathy trait testing, full disclosure must be provided that in some circumstances, the issue of paternity may be disclosed. For this reason and because of healthcare privacy, we always seek permission for the genetic testing and to ensure confidentiality, we report the hemoglobinopathy trait results back separately to each parent during separate visits.

In the United States, sickle cell disease is the most common genetic disorder identified through the state-mandated newborn screening program, occurring in 1:2,647. In regard to race in the United States, sickle cell disease occurs in African-Americans at a rate of 1:396 births, and in Hispanics at a rate of 1:36,000 births. In the United States, an estimated 90,000 people are affected by sickle cell disease, with an ethnic distribution of 90% African-American and 10% Hispanic. The United States sickle cell disease population represents a fraction of the worldwide burden of the disease, with global estimates of 312,000 neonates born annually with HbSS disease.

CLINICAL MANIFESTATIONS AND TREATMENT OF SICKLE CELL ANEMIA (HB SS)

Fever and Bacteremia

Fever in a child with sickle cell anemia is a medical emergency, requiring prompt medical evaluation and delivery of antibiotics because of the increased risk of bacterial infection and subsequent high mortality rate. Infants with sickle cell anemia, as early as 6 mo of age, develop abnormal immune function due to splenic infarction. By 5 yr of age, most children with sickle cell anemia have complete functional asplenia. Regardless of age, all patients with sickle cell anemia are at increased risk of infection and death from bacterial infection, particularly encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae type b*, and *Neisseria meningitidis*.

The rate of bacteremia in children with sickle cell disease, presenting with fever in busy pediatric emergency department is less than 1%. Several clinical strategies have been developed to manage children with sickle cell anemia who present with fever. These vary from hospital admission for intravenous (IV) antimicrobial therapy to administering a 3rd-generation cephalosporin in an emergency department or outpatient setting to patients without established risk factors for occult bacteremia (Table 462-2). Given the observation that the average time for a positive blood culture is <20 hr in children with sickle cell anemia, admission for 24 hr is probably the most prudent strategy for children and families who live out of town or who are identified as high risk for poor follow-up.

Outpatient management of fever without a source should be considered in children with the lowest risk of bacteremia and after intravenous ceftriaxone or other cephalosporin is given. Observation after antibiotic administration is important as children who have sickle cell anemia treated with ceftriaxone can develop severe, rapid, and life-threatening immune hemolysis. In the event that *Salmonella* spp. or *Staphylococcus aureus* bacteremia occurs, strong consideration should be given to an evaluation for osteomyelitis with a bone scan given the increased risk of osteomyelitis in children with sickle cell anemia when compared to the general population.

Aplastic Crisis

Human parvovirus B19 poses a unique threat for patients with sickle cell anemia because such infections result in temporary **red cell aplasia**, limiting the production of reticulocytes and causing profound anemia. Any child with sickle cell disease, fever, and reticulocytopenia should be considered to have parvovirus B19 until proven otherwise. The acute anemia of an aplastic crisis is treated conservatively using

Table 462-2	Clinical Factors Associated with Increased Risk of Bacteremia Requiring Admission in Febrile Children with Sickle Cell Disease
Seriously ill appearance	
Hypotension: systolic blood pressure <70 mm Hg at 1 yr of age or <70 mm Hg + 2 × the age in yr for older children	
Poor perfusion: capillary-refill time >4 sec	
Temperature >40.0°C (104°F)	
A corrected white-cell count >30,000/mm^3 or <5000/mm^3	
Platelet count <100,000/mm^3	
History of pneumococcal sepsis	
Severe pain	
Dehydration: poor skin turgor, dry mucous membranes, history of poor fluid intake, or decreased output of urine	
Infiltration of a segment or a larger portion of the lung	
Hemoglobin level <5.0 g/dL	

From Wilimas JA, Flynn PM, Harris S et al: A randomized study of outpatient treatment with ceftriaxone for selected febrile children with sickle cell disease, N Engl J Med *329:472–476, 1993.*

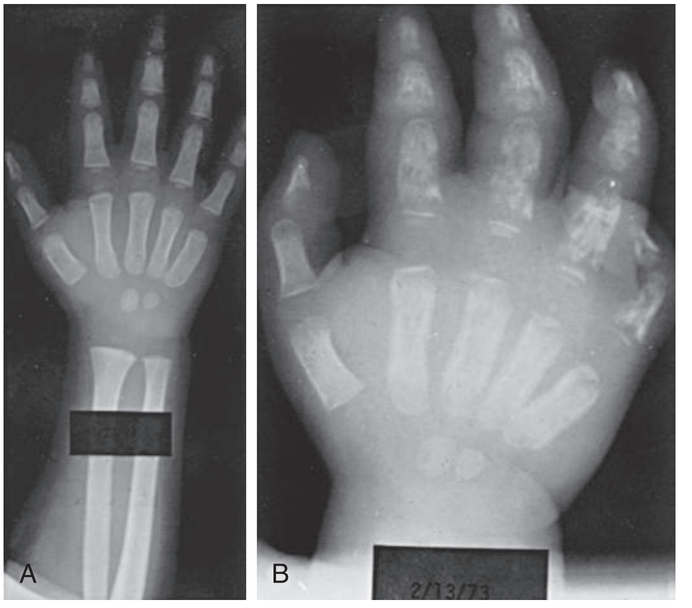

Figure 462-1 Roentgenograms of an infant with sickle cell anemia and acute dactylitis. **A,** The bones appear normal at the onset of the episode. **B,** Destructive changes and periosteal reaction are evident 2 wk later.

red blood cell transfusion when the patient becomes hemodynamically symptomatic or has a concurrent illness, such as acute chest syndrome. In addition, acute infection with parvovirus B19 is associated with pain, splenic sequestration, acute chest syndrome (ACS), glomerulonephritis, and stroke. Patients with parvovirus-associated aplastic crisis are contagious and infection precautions should be taken to avoid nosocomial spread of the infection.

Splenic Sequestration

Acute splenic sequestration is a life-threatening complication occurring primarily in infants and young children with sickle cell anemia. The incidence of splenic sequestration has declined from an estimated 30% to 12.6% with early identification by newborn screening and parental education. Sequestration can occur as early as 5 wk of age, but most often occurs in children between the ages of 6 mo and 2 yr.

Splenic sequestration is associated with rapid spleen enlargement causing left-sided abdominal pain and a decline in hemoglobin of at least 2 g/dL from the patient's baseline. Sequestration may lead to signs of hypovolemia as a result of the trapping of blood in the spleen; profound anemia, with total hemoglobin falling below 3 g/dL, has been reported. Reticulocytosis and a decrease in the platelet count may also be present. Sequestration may be triggered by fever, bacteremia, or viral infections.

Treatment includes early intervention and maintenance of hemodynamic stability using isotonic fluid or blood transfusions. Careful blood transfusions with red blood cells are recommended to treat both the sequestration and the resultant anemia. Blood transfusion aborts the red blood cell sickling in the spleen and allows release of the patient's blood cells that have become sequestered, often raising the hemoglobin above baseline values. We typically recommend only 5 mL/kg of red blood cells because the goal is to prevent hypovolemia. Blood transfusion that results in hemoglobin levels above 10 g/dL may put the patient at risk for hyperviscosity syndrome because of the risk that that patient may release the blood within the spleen.

Repeated episodes of splenic sequestration are common, occurring in two-thirds of patients. Most recurrent episodes develop within 6 mo of the previous episode. Prophylactic splenectomy performed after an acute episode has resolved is the only effective strategy for preventing future life-threatening episodes. Although blood transfusion therapy has been used with the goal of preventing subsequent episodes, evidence strongly suggests this strategy does not reduce the risk of recurrent splenic sequestration when compared to no transfusion therapy. Furthermore, prophylactic blood transfusion therapy may put the patient at risk for autotransfusion (the phenomenon when the blood sequestered in the spleen is released and dramatically increases the hemoglobin concentration, putting the patient at risk for hyperviscosity syndrome).

Hepatic and Gallbladder Involvement

See Chapters 360 and 366.

Sickle Cell Pain

Dactylitis, referred to as **hand-foot syndrome**, is often the first manifestation of pain in infants and young children with sickle cell anemia, occurring in 50% of children by their 2nd yr of life (Fig. 462-1). Dactylitis often manifests with symmetric or unilateral swelling of the hands and/or feet. Unilateral dactylitis can be confused with osteomyelitis, and careful evaluation to distinguish between the two is important because treatment differs significantly. Dactylitis requires palliation with pain medications, such as hydrocodone, whereas osteomyelitis requires at least 4-6 wk of IV antibiotics. Given the recent association between genotype and metabolism of codeine, a subgroup of children may not get pain relief from codeine. Hence, feedback from the parents is needed to determine if therapy was successful in relieving pain.

The cardinal clinical feature of sickle cell anemia is **acute vasoocclusive pain**. No written definition can describe the visual picture of a child with sickle cell anemia experiencing pain. Acute sickle cell pain is characterized as unremitting discomfort that can occur in any part of the body but most often occurs in the chest, abdomen, or extremities. These painful episodes are often abrupt and cause disruption of daily life activities and anguish for children and their caregivers. A patient with sickle cell anemia has approximately 1 painful episode per year that requires medical attention.

The exact etiology of pain is unknown, but the pathogenesis is initiated when blood flow is disrupted in the microvasculature by sickled cells, resulting in tissue ischemia. Acute sickle cell pain may be precipitated by physical stress, infection, dehydration, hypoxia, local or systemic acidosis, exposure to cold, and swimming for prolonged periods. Successful treatment of painful episodes requires education of both the caregivers and patients regarding the recognition of symptoms and the optimal management strategy. Given the absence of any

reliable objective laboratory or clinical parameter associated with pain, trust between the patient and the treating physician is paramount to successful clinical management. Specific therapy for pain varies greatly but generally includes the use of acetaminophen or a nonsteroidal antiinflammatory agent early in the course of pain, followed by escalation to a combination analgesic such as hydrocodone, or to a single-agent short- or long-acting oral opioid.

Some patients require hospitalization for administration of intravenous morphine or derivatives of morphine. The incremental increase and decrease in the use of the medication to relieve pain roughly parallels the 8 phases associated with a chronology of pain and comfort (Table 462-3). The average hospital length of stay for children admitted in pain is 4.4 days. The American Pain Society has published clinical guidelines for treating acute and chronic pain in patients with sickle cell disease of any type. These recommendations are comprehensive and represent a starting point for treating pain (http://www.ampainsoc.org/pub/sc.htm).

The only measure for degree of pain is the patient. Healthcare providers working with children in pain should use a consistent, validated pain scale, such as the Wong-Baker FACES Scale for assessing pain. Although pain scales have proved useful for some children, others require prenegotiated activities to determine when opioid therapy should be initiated and decreased. For instance, sleeping through the night might be an indication for decreasing pain medication by 20% the following morning. The majority of painful episodes in patients with sickle cell anemia are managed at home with comfort measures, such as heating blanket, relaxation techniques, massage, and oral pain medication.

Several myths have been propagated regarding the treatment of pain in sickle cell anemia. The concept that painful episodes in children should be managed without opioids is without foundation and results in unwarranted suffering on the part of the patient. Blood transfusion therapy during an existing painful episode does not decrease the intensity or duration of the painful episode as tissue necrosis occurs well before the ability to administer the transfusion. Intravenous hydration does not relieve or prevent pain and is appropriate when the patient is dehydrated or unable to drink as a result of the severe pain. *Opioid dependency in children with sickle cell anemia is rare and should never be used as a reason to withhold pain medication.* However, patients with multiple painful episodes requiring hospitalization within a year or with pain episodes that require hospitalization for more than 7 days should be evaluated for comorbidities and environmental stressors that are contributing to the frequency or duration of pain. Children with chronic pain should be evaluated for other reasons associated with vasoocclusive pain episodes, including, but not limited to, overexertion with physical activities, such as participating in the school band, sports, or heavy lifting of backpacks to and from school and up and down steps. A careful history is warranted to distinguish chronic pain that often is not relieved by opioids alone versus acute unremitting vasoocclusive pain episodes.

Skeletal pain (bone or bone marrow infarction) with or without fever must be differentiated from osteomyelitis. Both *Salmonella* spp. and *S. aureus* cause osteomyelitis in children with sickle cell anemia, which is often in the diaphysis of long bones (in contrast to children without sickle cell anemia where osteomyelitis is in the metaphyseal region of the bone). Differentiating osteonecrosis from a vasoocclusive

Table 462-3 Summary of the Chronology of Pain in Children with Sickle Cell Disease

PHASE	PAIN CHARACTERISTICS	SUGGESTED COMFORT MEASURES USED
1 (Baseline)	No vasoocclusive pain; pain of complications may be present, such as that connected with avascular necrosis of the hip	No comfort measures used
2 (Prepain)	No vasoocclusive pain; pain of complications may be present; prodromal signs of impending vasoocclusive episode may appear, e.g., "yellow eyes" and/or fatigue	No comfort measures used; caregivers may encourage child to increase fluids to prevent pain event from occurring
3 (Pain start point)	First signs of vasoocclusive pain appear, usually in mild form	Mild oral analgesic often given; fluids increased; child usually maintains normal activities
4 (Pain acceleration)	Intensive of pain increases from mild to moderate Some children skip this level or move quickly from phase 3 to phase 5	Stronger oral analgesic are given; rubbing, heat, or other activities are often used; child usually stays in school until the pain becomes more severe, then stays home and limits activities; is usually in bed; family searches for ways to control the pain
5 (Peak pain experience)	Pain accelerates to high moderate or severe levels and plateaus; pain can remain elevated for extended period Child's appearance, behavior, and mood are significantly different from normal	Oral analgesics are given around the clock at home; combination of comfort measures is used; family might avoid going to the hospital; if pain is very distressing to the child, parent takes the child to the emergency department After child enters the hospital, families often turn over comforting activities to healthcare providers and wait to see if the analgesics work Family caregivers are often exhausted from caring for the child for several days with little or no rest
6 (Pain decrease start point)	Pain finally begins to decrease in intensity from the peak pain level	Family caregivers again become active in comforting the child but not as intensely as during phases 4 and 5
7 (Steady pain decline)	Pain decreases more rapidly, become more tolerable for the child Child and family are more relaxed	Healthcare providers begin to wean the child from the IV analgesic; oral opioids given; discharge planning is started Children may be discharged before they are pain free
8 (Pain resolution)	Pain intensity is at a tolerable level, and discharge is imminent Child looks and acts like "normal" self; mood improves	May receive oral analgesics

Adapted from Beyer JE, Simmons LE, Woods GM, et al: A chronology of pain and comfort in children with sickle cell disease, Arch Pediatr Adolesc Med *153:913–920, 1999.*

crisis and osteomyelitis is often difficult; patients with osteomyelitis often have a longer duration of fever and pain, swelling of the affected area, fewer or only 1 location of pain *and* tenderness, higher white blood cell counts, and an elevated C-reactive protein. Blood cultures, when positive, are helpful.

Imaging studies, which must include MRI with contrast, are helpful in distinguishing osteomyelitis from bone or marrow infarction, although rarely an osteomyelitis may initially appear "cold" (infarctive osteomyelitis), whereas an infarct, over time, may appear hyperemic as it heals. Both lesions may demonstrate marrow signal intensity abnormalities, periosteal elevation, and bone, periosteal, or extraosseous fluid collections. MRI findings suggestive of osteomyelitis include localized medullary fluid, sequestrum, and cortical defects. Ultimately, aspiration with or with or without biopsy and culture will be needed to differentiate the 2 processes (see Chapter 684).

Avascular Necrosis

Avascular necrosis (AVN) occurs at a higher rate among children with sickle cell anemia than in the general population, and is a source of both acute and chronic pain. Most commonly, the femoral head is affected and AVN. Unfortunately, the AVN of the hip may cause limp and leg-length discrepancy. Other sites affected include the humeral head and mandible. Risk factors for AVN include HbSS disease with α-thalassemia trait, frequent vasoocclusive episodes, and elevated hematocrit (for patients with sickle cell anemia). Optimal treatment of AVN has not been determined and individual management requires consultation with the disease-specific specialist, orthopedic surgeon, physical therapist, hematologist and primary care physician. Initial management may include referral to a physical therapist to address strategies to increase strength and decrease weight bearing daily activities that may exacerbate the pain associated with AVN. Opioids are often used, but usually can be tapered after the acute pain has subsided with AVN. Regular blood transfusion therapy has not been demonstrated as an effective therapy to abate the acute and chronic pain associated AVN.

Priapism

Priapism is defined as an unwanted painful erection of the penis and most commonly affects males with sickle cell anemia. The mean age of first episode is 15 yr, although priapism has been reported in children as young as 3 yr. The actuarial probability of a patient experiencing priapism is approximately 90% by 20 yr of age.

Priapism occurs in 2 patterns: prolonged, lasting more than 4 hr, or stuttering, with brief episodes that resolve spontaneously but may occur in clusters and herald a prolonged event. Both types occur from early childhood to adulthood. Most episodes occur between 3 A.M. and 9 A.M. Priapism in sickle cell disease represents a low flow state caused by venous stasis from sickling of red blood cells in the corpora cavernosa. Recurrent prolonged episodes of priapism are associated with impotence.

The optimal treatment for acute priapism is unknown. Acutely, supportive therapy, such as a hot shower, short aerobic exercise, or pain medication, is commonly used by patients at home. A prolonged episode lasting >4 hr should be treated by aspiration of blood from the corpora cavernosa followed by irrigation with dilute epinephrine to produce immediate and sustained detumescence. Urology consultation is required to initiate this procedure, with appropriate input from a hematologist. Simple blood transfusion and exchange transfusion has been proposed for the acute treatment of priapism, but limited evidence supports this strategy as the initial management. We typically refer a patient to the urology service first, and if no benefit is obtained from surgical management, consider transfusion therapy. However, detumescence may not occur for up to 24 hr (far longer than with urologic aspiration) after transfusion and transfusion for priapism has been associated with acute neurologic events.

Neurologic Complications

Neurologic complications associated with sickle cell anemia are varied and complex, ranging from *acute* ischemic stroke with focal neurologic deficit to clinically *silent* abnormalities found on radiologic imaging. Prior to the development of transcranial Doppler to screen for stroke risk among children with sickle cell anemia, approximately 11% experienced an overt stroke and 20% a silent stroke before their 18th birthday. A functional definition of overt stroke is the presence of a focal neurologic deficit lasting for >24 hr and/or abnormal neuroimaging of the brain indicating a cerebral infarct on T2-weighted magnetic resonance imaging (MRI) corresponding to the focal neurologic deficit (Figs. 462-2 and 462-3). A silent cerebral infarct, as its name indicates, lacks focal neurologic findings lasting >24 hr and is diagnosed by abnormal imaging on T2-weighted MRI. Children with other

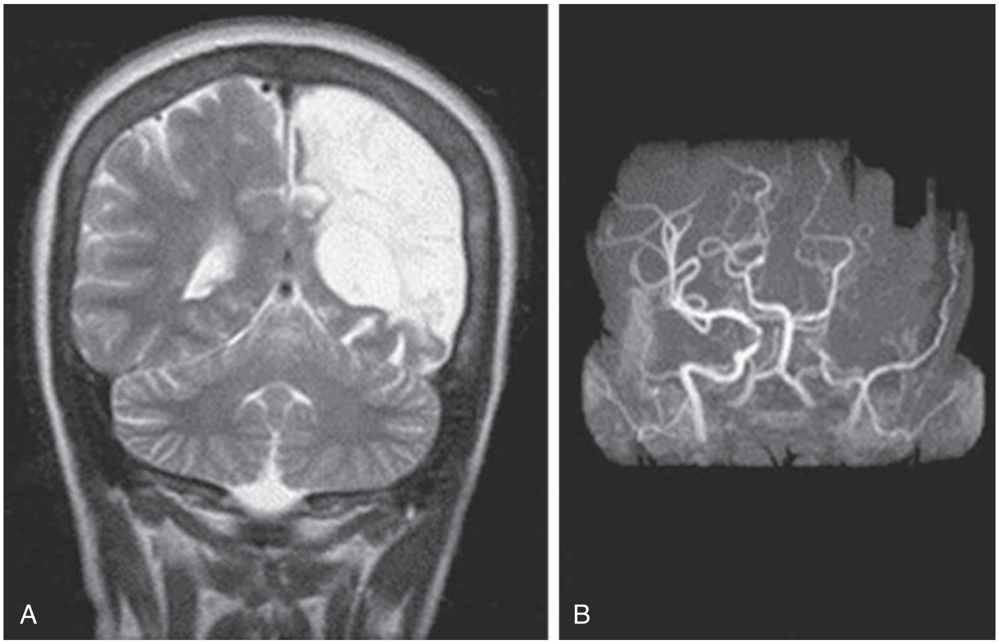

Figure 462-2 T2-weighted MRI and magnetic resonance angiography of the brain. **A,** T2-weighted MRI shows remote infarction of the territories of the left anterior cerebral artery and middle cerebral artery. **B,** Magnetic resonance angiography shows occlusion of the left internal carotid artery siphon distal to the takeoff of the ophthalmic artery.

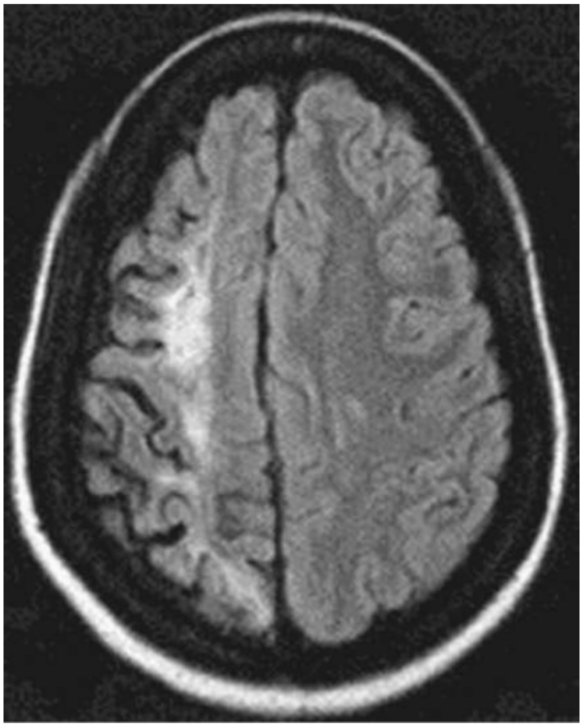

Figure 462-3 Fast fluid-attenuated inversion recovery sequence MRI of the brain showing a right hemisphere border-zone cerebral infarction in a child with sickle cell anemia. *(From Switzer JA, Hess DC, Nichols F, et al: Pathophysiology and treatment of stroke in sickle-cell disease: present and future.* Lancet Neurol *5:501–512, 2006.)*

types of sickle cell disease, such as HbSC or HbSβ-thalassemia+, develop overt or silent cerebral infarcts as well, but at a lower frequency than children with HbSS and HbSβ-thalassemia zero. Other neurologic complications include headaches that may or may not correlate to degree of anemia, seizures, cerebral venous thrombosis and reversible posterior leukoencephalopathy syndrome, also referred to as posterior reversible encephalopathy syndrome (PRES).

For patients presenting with acute focal neurologic deficit, a prompt pediatric neurologic evaluation is recommended, as well as consultation with a pediatric hematologist. In addition, oxygen administration to keep oxygen saturations >96% and simple blood transfusion within 1 hr of presentation with a goal of increasing the hemoglobin to a maximum of 10 g/dL is warranted. A timely simple blood transfusion is important because this is the most efficient strategy to dramatically increase oxygen content of the blood, if the oxygen saturation is above 96%. To exceed this hemoglobin threshold limits oxygen delivery to the brain as a result of hyperviscosity by increasing the hemoglobin significantly over the patient's baseline values. Subsequently, prompt treatment with an exchange transfusion should be considered, either manually or with automated erythrocytapheresis, to reduce the HbS percentage to at least <50%, and ideally to <30%. Exchange transfusion at the time of acute stroke is associated with a decreased risk of second stroke when compared to simple transfusion alone. Computed tomography (CT) of the head to exclude cerebral hemorrhage should be performed as soon as possible, and if available, MRI of the brain with diffusion-weighted imaging to distinguish between ischemic infarcts and PRES. Magnetic resonance (MR) venography is useful to evaluate the possibility of cerebral venous thrombosis, a rare but potential cause of focal neurologic deficit in children with sickle cell disease. MR angiography may identify evidence of cerebral vasculopathy; these images are not critical in the initial time management of a child with sickle cell disease presenting with a focal neurologic deficit.

The clinical presentation of PRES or central venous thrombosis can mimic a stroke but would require a different treatment course. For both PRES and cerebral venous thrombosis, the optimal management has not been defined in patients with sickle cell disease, resulting in the need for consultation with both a pediatric neurologist and a pediatric hematologist.

Transcranial Doppler Ultrasonography

Primary prevention of overt stroke can be accomplished using **transcranial Doppler ultrasonography** (TCD) assessment of the blood velocity in the terminal portion of the internal carotid and the proximal portion of the middle cerebral artery. Children with sickle cell anemia with an elevated time-averaged mean maximum (TAMM) blood-flow velocity >200 cm/sec are at increased risk for a cerebrovascular event. A TAMM measurement of <200 cm/sec but ≥180 cm/sec represents a conditional threshold. A repeat measurement is suggested within a few months because of the high rate of conversion to a TCD velocity >200 cm/sec in this group of patients.

Two distinct methods of measuring TCD velocity exist: a nonimaging and an imaging technique. The nonimaging technique was the method used in the TCD trial sponsored by the National Institutes of Health, whereas most pediatric radiologists in practice use the imaging technique. When compared to each other, the imaging technique produces values that are 10-15% below that of the nonimaging technique. The imaging technique uses the time-averaged mean of the maximum velocity (TAMX), and this measure is believed to be equivalent to the nonimaging calculation of TAMM. A downward adjustment for the transfusion threshold is appropriate for centers using the imaging method to assess TCD velocity. The magnitude of the transfusion threshold in the imaging technique has not been settled, but a transfusion threshold of a TAMX of 185 cm/sec and a conditional threshold of TAMX of 165 cm/sec, seems reasonable.

The primary approach for prevention of recurrent overt stroke is blood transfusion therapy aimed at keeping the maximum HbS concentration <30%. Despite regular blood transfusion therapy, around 20% of patients will have a second stroke and 30% of this group will have a third stroke. Children with TCD values above defined thresholds should begin chronic blood transfusion therapy to maintain HbS levels <30% to decrease the risk of first stroke. This strategy results in an 85% reduction in the rate of overt strokes. Once transfusion therapy is initiated, patients are expected to continue it indefinitely as discontinuation of blood transfusion therapy is associated with an increase in the development of silent infarcts.

Pulmonary Complications

Lung disease in children with sickle cell anemia is the second most common reason for hospital admission and is associated with significant mortality. ACS refers to a life-threatening pulmonary complication of sickle cell disease defined as a new radiodensity on chest radiography plus any 2 of the following: fever, respiratory distress, hypoxia, cough, or chest pain (Fig. 462-4). Even in the absence of respiratory symptoms, all patients with fever should receive a chest radiograph to identify evolving ACS because clinical examination alone is insufficient to identify patients with a new radiographic density and early detection of ACS will alter clinical management. The radiographic findings in ACS are variable but may include single lobe involvement, predominantly left lower lobe; multiple lobes, most often both lower lobes; and pleural effusions, either unilateral or bilateral. ACS may progress rapidly from a simple infiltrate to extensive infiltrates and a pleural effusion. Therefore, continued pulse oximetry and frequent clinical exams are required, and repeat chest x-rays are indicated for progressive hypoxia, dyspnea, tachypnea, and other signs of respiratory distress.

The majority of patients with ACS do not have a single identifiable cause. Infection is the most well-known etiology, yet only 30% of ACS episodes will have positive sputum or bronchoalveolar culture, and the most common pathogens are *S. pneumoniae*, *Mycoplasma pneumoniae,* and *Chlamydia* sp. The most frequent event preceding ACS is a painful episode requiring systemic opioid treatment. Fat emboli has also been implicated as a cause of ACS, arising from infarcted bone marrow, and can be life-threatening if large amounts are released to the lungs. Fat

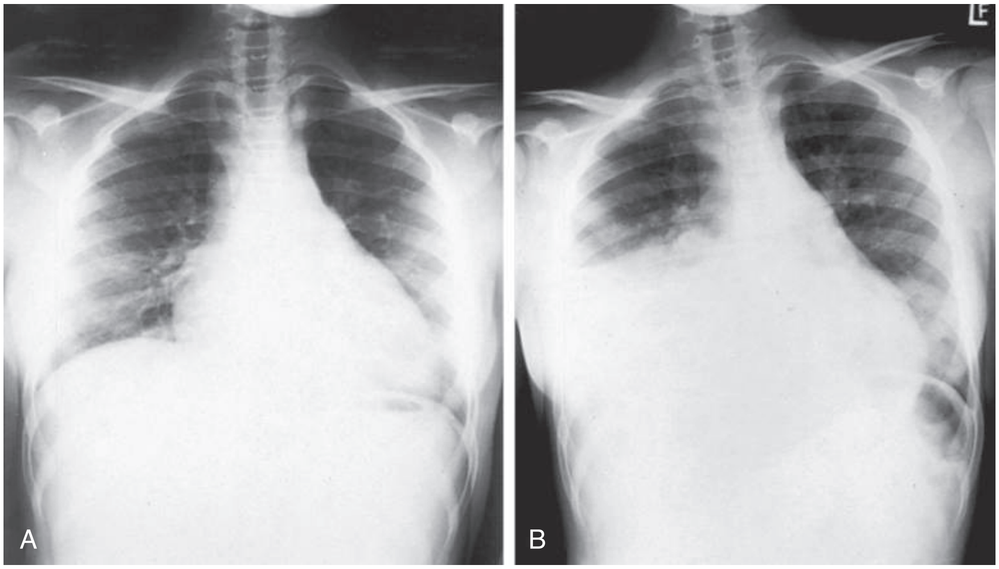

Figure 462-4 **Probable pulmonary infarction in a 15 yr old patient with Hb-SS. A,** Frontal radiograph shows consolidation and a small pleural effusion posteriorly in the right lower lobe. **B,** Radiograph obtained <24 hr later shows massive right middle and lower lobe consolidation and effusion. No organisms could be cultured. The diagnosis of "probably pulmonary infarction" was established clinically. *(Courtesy of Dr. Thomas L. Stovis, Children's Hospital of Michigan, Detroit, MI. From Kuhn JP, Slovis TL, Haller JO:* Caffey's pediatric diagnostic imaging, *vol 1, ed 10, Philadelphia, 2004, Mosby, p. 1087.)*

emboli can be difficult to diagnose but should be considered in any patient with sickle cell disease, presenting with rapid onset of respiratory distress and altered mental status changes. Petechial rash, may also occur, but may be difficult to detect if not looked for carefully.

Given that the causes of ACS are varied, recommended management is also multimodal (Table 462-4). The type of opioid, with morphine being more likely to cause ACS than nalbuphine hydrochloride, is associated with an increase in the risk of ACS in part because of hypoventilation. However, under no circumstance should opioid administration be limited to prevent ACS; rather, care must be taken to prevent ACS from developing. In patients with chest pain, regular use of an incentive spirometer at 10-12 breaths every 2 hr can significantly reduce the frequency of subsequent acute chest pain episodes. As a result of the clinical overlap between pneumonia and ACS, all episodes should be treated promptly with antimicrobial therapy, including at least a macrolide and possibly a third-generation cephalosporin. A previous diagnosis of asthma or airway hyperresponsiveness should prompt treatment following standard of care for an asthma exacerbation with corticosteroids and bronchodilators. The diagnosis of ACS does not negate the recommended management of a patient with asthma exacerbation. Oxygen should be administered for patients who demonstrate hypoxia. Blood transfusion therapy using either simple or exchange (manual or automated) transfusion is the only method to abort a rapidly progressing episode of ACS. The decision when to give blood and whether the transfusion should be a simple or exchange transfusion is less clearly defined. Commonly blood transfusions are given when at least 1 of the following clinical features are present: decreasing oxygen saturation, increasing work of breathing, rapid change in respiratory effort either with or without a worsening chest radiograph, a drop in hemoglobin of 2 g/dL below their baseline, or previous history of severe ACS requiring admission to the intensive care unit.

Pulmonary hypertension has been identified as a major risk factor for death in adults with sickle cell anemia. The natural history of pulmonary hypertension in children with sickle cell anemia is unknown. Optimal strategies for screening at risk patients have not been identified (echocardiogram results are not supported by right heart catheterization results demonstrating elevated pulmonary artery pressures) and the best diagnostic methodology carries significant risk of harm. Attempts to identify targeted therapeutic interventions to alter the natural history of pulmonary hypertension in adults have been unsuccessful.

Table 462-4	Overall Strategies for the Management of Acute Chest Syndrome
PREVENTION	
Incentive spirometry and periodic ambulation in patients admitted for sickle cell pain, surgery, or febrile episodes	
Watchful waiting in any hospitalized child or adult with sickle cell disease (pulse oximetry monitoring and frequent respiratory assessments)	
Cautious use of intravenous fluids	
Intense education and optimum care of patients who have sickle cell anemia and asthma	
DIAGNOSTIC TESTING AND LABORATORY MONITORING	
Blood cultures	
Nasopharyngeal samples for viral culture (respiratory syncytial virus, influenza)	
Blood counts every day and appropriate chemistries	
Continuous pulse oximetry	
Chest radiographs	
TREATMENT	
Blood transfusion (simple or exchange)	
Supplemental O_2 for drop in pulse oximetry by 4% over baseline, or values <90%	
Empirical antibiotics (third-generation cephalosporin and macrolide)	
Continued respiratory therapy (incentive spirometry and chest physiotherapy as necessary)	
Bronchodilators and steroids for patients with asthma	
Optimum pain control and fluid management	

Renal Disease and Enuresis

Renal disease among patients with sickle cell disease is a major comorbid condition that can lead to premature death. Seven sickle cell disease nephropathies have been identified: (1) gross hematuria, (2) papillary necrosis, (3) nephrotic syndrome, (4) renal infarction, (5) hyposthenuria, (6) pyelonephritis, and (7) renal medullary carcinoma. As expected, the presentation of these entities is varied but may include

hematuria, proteinuria, renal insufficiency, concentrating defects, or hypertension.

The common presence of nocturnal enuresis occurring in children with sickle cell anemia is not well defined but is troublesome to affected children and their parents. The overall prevalence of enuresis was 33% in the Cooperative Study of Sickle Cell Disease with the highest prevalence (42%) among children ages 6-8 yr. Furthermore, enuresis may still occur in approximately 9% of the older adolescent group. As would be the case in all children with nocturnal enuresis, we would systematically evaluate the children for recurrent urinary tract infections, kidney function, and possibly obstructive sleep apnea syndrome with a supportive history. Unfortunately, most children with nocturnal enuresis do not have an etiology and targeted therapeutic interventions have been of limited success.

Cognitive and Psychological Complications

As with any child with a chronic illness, good health maintenance must include routine psychological and social assessment. Ongoing evaluation of the family unit and identification of the resources available to cope with a chronic illness are critical for optimal management. Children and adolescents with sickle cell disease also have decreased quality of life, as measured on standardized assessments, compared to their siblings and children with other chronic diseases. Furthermore, children with sickle cell disease are at great risk for academic failure and have a 20% high school graduation rate. One reason behind the low high school graduation rate is that approximately a third of children with sickle cell anemia have had a cerebral infarct—either silent cerebral infarcts or overt strokes. Children with cerebral infarcts require ongoing cognitive and school performance assessment so that education resources can be focused to optimize educational attainment. Relevant support groups and attendance in group activities, such as camps for children with sickle cell disease, may be of direct benefit by improving self-esteem and establishing peer relationships.

Other Complications

In addition to the previously mentioned organ dysfunctions, patients with sickle cell anemia can have other significant complications. These complications include, but are not limited to sickle cell retinopathy, delayed onset of puberty, and leg ulcers. Optimal treatment for each of these entities has not been determined and individual management requires consultation with the disease-specific specialist, a hematologist, and primary care physician.

THERAPEUTIC CONSIDERATIONS

Hydroxyurea

Hydroxyurea, a myelosuppressive agent, is the only drug proven effective in reducing the frequency of painful episodes. In a large clinical trial of adults with sickle cell anemia, hydroxyurea was found to decrease the rate of hospitalization for painful episodes by 50% and the rate of ACS and blood transfusion by almost 50%. Follow-up of the original trial found that adults taking hydroxyurea had shorter hospital stays and required less pain medication during hospitalization. In children with sickle cell anemia, a safety feasibility trial of hydroxyurea demonstrated that hydroxyurea was safe and well tolerated in children >5 yr of age. No clinical adverse events were identified in this study; the primary toxicities were limited to myelosuppression that reversed upon cessation of the drug. Infants treated with hydroxyurea also experienced fewer episodes of pain, dactylitis, and ACS, and were less-often hospitalized or received a blood transfusion. Despite being a myelosuppressive agent, the infants treated with hydroxyurea did not experience increased rates of bacteremia or serious infection.

Hydroxyurea may be indicated for other sickle cell–related complications, especially in patients who are unable to tolerate other treatments. For patients who either will not or cannot continue blood transfusion therapy to prevent recurrent stroke, hydroxyurea therapy may be a reasonable alternative. The trial assessing the efficacy of hydroxyurea as an alternative to transfusions to prevent second stroke was terminated early after the data safety and monitoring found an increased stroke rate in the hydroxyurea arm compared to the transfusion arm (0 vs. 7 [10%]). Hydroxyurea alone is inferior to transfusion therapy for secondary stroke prevention in patients who do not have contraindications to ongoing transfusions. Although not investigated as a primary outcome, hydroxyurea appears to have promise for the prevention of recurrent priapism. One study found hydroxyurea decreased glomerular hyperfiltration in young children with sickle cell anemia.

The long-term toxicity associated with initiating hydroxyurea in very young children has not yet been established. However, all evidence to date suggests that the benefits far outweigh the risks. For these reasons, children >2 yr of age receiving hydroxyurea require well-informed parents and medical care by pediatric hematologists, or at least comanagement by a physician with expertise in immunosuppressive medications. The typical starting dose of hydroxyurea is 15-20 mg/kg given once daily, with an incremental dosage increase every 8 wk of 5 mg/kg, and if no toxicities occur, up to a maximum of 35 mg/kg per dose. The infant hydroxyurea study found young children could safely be started at 20 mg/kg/day without increased toxicity. Achievement of the therapeutic effect of hydroxyurea can require several months, and for this reason, inpatient initiating of hydroxyurea is not optimal. We prefer to introduce the concept to parents within the first year of life, provide literature that describes both the pros and cons of starting hydroxyurea in children with severe symptoms of sickle cell disease, and educate parents on starting hydroxyurea in asymptomatic children as a preventative therapy for repetitive pain and ACS events. Other effects of hydroxyurea that may vary include an increase in the total hemoglobin level and a decrease in the TCD velocity.

Hematopoietic Stem Cell Transplantation

The only cure for sickle cell anemia is transplantation with human leukocyte antigen (HLA)–matched **hematopoietic stem cells** from a sibling or unrelated donor. The most common indications for transplant are recurrent ACS, stroke and abnormal TCD. Sibling-matched stem cell transplantation has a lower risk for graft-versus-host disease than unrelated donors. However, few children have suitable sibling donors. Stem cell transplantation using an unrelated but well-matched donor is the subject of an open clinical trial. The decision to consider unrelated transplantation should involve appropriate consultation and counseling from physicians with expertise in sickle cell transplantation.

Stem cell transplantation for children with sickle cell disease with a genetically matched sibling is not routinely done, in part because of the known risk of transplantation-related mortality and morbidity in a short period of time, commonly less than 2 yr after the transplantation versus the high probability that patients will live to and through adulthood. The use of hydroxyurea has dramatically decreased the disease burden for the patient and family, with associated far fewer hospitalizations for pain or ACS episodes and less use of blood transfusions. Furthermore, the field of stem cell transplantation is progressing so rapidly that in a decade or less haplo-identical transplantation will be considered a viable option for not only individuals with severe disease, but also those with less-severe manifestations. Haplo-identical transplantations in adults with severe manifestations of sickle cell disease resulted in no deaths, and approximately 60% of the participants were cured of the disease. Low intensity, nonmyeloablative HLA-matched sibling allogenic stem cell transplantation has been employed in patients ≥16 years of age.

Red Blood Cell Transfusions

Red blood cell transfusions are frequently used in the management of children with sickle cell anemia, both in the treatment of acute complications such as ACS, aplastic crisis, splenic sequestration, and acute stroke, and to prevent surgery-related ACS and first stroke in patients with abnormal TCD or MRI findings (silent stroke). Patients with sickle cell disease are at increased risk of developing alloantibodies to less-common red cell surface antigens after receiving even a single transfusion. In addition to standard cross-matching for major blood group antigens (A, B, O, RhD), more extended matching should be performed to identify donor units that are C-, E-, and Kell-antigen

negative. Some centers have begun to perform full red blood cell phenotyping for patients receiving chronic blood transfusions.

Three methods of blood transfusion therapy are used in the management of acute and chronic complications associated with sickle cell anemia: automated erythrocytapheresis, manual exchange transfusion (phlebotomy of a set amount of patient's blood followed by rapid administration of donated packed red blood cells), and simple transfusion. Automated erythrocytapheresis is the preferred method for patients requiring chronic blood transfusion therapy because there is a minimum net iron balance after the procedure, followed by manual exchange transfusion. Simple transfusion therapy is the least-preferable method for regular blood transfusion therapy because this strategy results in the highest net-positive iron balance after the procedure. Despite being the preferred method, erythrocytapheresis is less-frequently performed because of the requirement of technical expertise, large venous access, multiple units of matched red blood cells, and an available cytapheresis machine.

Preparation for surgery for children with sickle cell disease requires a coordinated effort between the hematologist, surgeon, and primary care provider. ACS and pain are the 2 most common postoperative complications, with ACS being a significant risk factor for postoperative death. Blood transfusion prior to surgery for children with sickle cell anemia is recommended to raise the hemoglobin level preoperatively to no more than 10 g/dL, although benefit also may be seen at lower hemoglobin values. The rate of serious complications, including a higher rate of ACS in patients who do not receive blood transfusion when compared to those who do. When available, blood transfusion therapy prior to surgery should be the standard approach. When preparing a child with sickle cell anemia for surgery with a simple blood transfusion, caution must be used not to elevate the hemoglobin beyond 10 g/dL because of the risk of hyperviscosity syndrome. For children with sickle cell anemia, exchange transfusion prior to surgery is of no greater benefit than simple blood transfusion and carries significantly higher risk of red blood cell alloimmunization. For children with milder forms of sickle cell disease, such as HbSC or HbSβ-thalassemia, a decision must be made on a case-by-case basis as to whether an exchange transfusion is warranted, because a simple transfusion may raise the hemoglobin to an unacceptable level.

Excessive Iron Stores

The primary toxic effect of blood transfusion therapy relates to **excessive iron stores**, which can result in organ damage and premature death. Excessive iron stores develop after 100 mL/kg of red cell transfusion or about 10 transfusions. The assessment of iron overload in children receiving regular blood transfusions is difficult. The most commonly used and least-invasive method of estimating total-body iron involves serum ferritin levels. Ferritin measurements have significant limitations in their ability to estimate iron stores for several reasons, including, but not limited to, elevation during acute inflammation and poor correlation with excessive iron in specific organs after 2 yr of regular blood transfusion therapy. Advances in technology have improved the assessment of iron stores among children with sickle cell disease receiving regular blood transfusion therapy. MRI of the liver has proven to the most effective and common approach for assessment of iron stores. The imaging strategy is more accurate than serum ferritin in measuring heart and liver iron content. MRI T2* and MRI R2 and R2* sequences are now being used to estimate iron levels in the heart and liver. The standard for iron assessment previously was biopsy of the liver, which is an invasive procedure exposing children to the risk of general anesthesia, bleeding, and pain. Liver biopsy alone does not accurately estimate total-body iron, as iron deposition in the liver is not homogenous and varies among the affected organs; that is, the amount of iron found in the liver is not equivalent to cardiac tissues. The major advantage of a liver biopsy is that histologic assessment of the parenchyma can be ascertained along with appropriate staging of suspected pathology, particularly cirrhosis.

The primary treatment of excessive iron stores resulting from red blood cell transfusion requires iron chelation using medical therapy. In the United States, 3 chelating agents are commercially available and approved for use in transfusional iron overload. Deferoxamine is administered subcutaneously 5 of 7 nights/wk for 10 hr a night. Deferasirox is an effervescent tablet that is dissolved in liquid and taken by mouth daily, and deferiprone is available in tablets taken orally twice a day. The FDA approved deferasirox, the newest orally administered chelator, in 2005 for use in patients age ≥2 yr. Deferiprone is an older oral chelator that has been widely used outside of the United States for many years and was approved by the FDA in 2011, but requires weekly monitoring of complete blood counts because of a risk of neutropenia throughout therapy. Transfusion-related excessive iron stores in children with sickle cell disease should be managed by a physician with expertise in chelation therapy owing to the risk of significant toxicity from available chelation therapies.

OTHER SICKLE CELL SYNDROMES

The most commonly occurring sickle cell syndromes besides HbSS are HbSC, HbSβ-thalassemia zero, and HbSβ-thalassemia+. The other syndromes—HbSD, HbSO^{Arab}, HbS HPFH, and other variants—are much less common. Patients with HbSβ-thalassemia zero have a clinical phenotype similar to those with HbSS. HbSC does not polymerize like HbSS, but crystals of HbC interact with membrane ion transport, dehydrating red cells and inducing sickling. Children who have HbSC disease can experience the same symptoms and complications as those with severe HbSS disease, but the frequency of such experience is less. Children with HbSC also have increased incidence of retinopathy, chronic hypersplenism, splenic sequestration, and renal medullary carcinoma. The natural history of the other sickle cell syndromes is variable and difficult to predict because of the lack of systematic evaluation.

There is no validated model that can predict the clinical course of an individual with sickle cell disease. A patient with HbSC can have a more-severe clinical course than a patient with HbSS. Management of end-organ dysfunction in children with sickle cell syndromes requires the same general principles as managing patients with sickle cell anemia; however, each situation should be managed on a case-by-case basis and requires consultation with a pediatric hematologist.

ANTICIPATORY GUIDANCE

The 2 primary goals of pediatric care are to promote health and prevent disease. Children with sickle cell disease should receive general health maintenance as recommended for all children with special attention to the following disease specific guidance.

Spleen Palpation

Splenomegaly is a common complication of sickle cell anemia and splenic sequestration can be life-threatening. Parents and primary caregivers should be taught how to palpate the spleen to determine if the spleen is enlarging starting at the first visit with reinforcement at subsequent visits. Parents should also demonstrate spleen palpation to the provider.

Prophylactic Penicillin

Children with sickle cell anemia should receive prophylactic oral penicillin VK until at least 5 yr of age (125 mg twice a day up to age 3 yr, and then 250 mg twice a day thereafter). No established guidelines exist for penicillin prophylaxis beyond 5 yr of age, and some clinicians continue penicillin prophylaxis, whereas others recommend discontinuation. Continuation of penicillin prophylaxis should be continued beyond 5 yr of age in children with history of pneumococcal infection because of the increased risk of a recurrent infection. An alternative for children who are allergic to penicillin is erythromycin ethyl succinate 10 mg/kg twice a day.

Immunizations

In addition to penicillin prophylaxis, routine childhood immunizations, as well as the annual administration of influenza vaccine, are highly recommended. Children with sickle cell anemia develop functional asplenia and also require immunizations to protect against encapsulated organisms including additional pneumococcal and meningococcal vaccinations. Vaccination guidelines can be found at

the Centers for Disease Control and Prevention website: http://www.immunize.org/catg.d/p2010.pdf.

Transcranial Doppler Ultrasound

Primary stroke prevention using TCD has resulted in a decrease in the prevalence of overt stroke among children with sickle cell anemia. Children with HbSS or HbSβ-thalassemia zero should be screened annually with TCD starting at age 2 yr. TCD is best performed when the child is quietly awake and in their usual state of health. TCD measurements may be falsely elevated in the setting of acute anemia or falsely low immediately after blood transfusions or if procedural sedation is used. Screening should occur annually from age 2-16 yr. Abnormal values should be repeated within 2-4 wk to identify patients at greatest risk of overt stroke. Conditional values should be repeated within 3 mo, and normal values repeated annually. Routine neuroimaging with MRI in asymptomatic patients is not currently recommended.

Hydroxyurea

Monitoring children on hydroxyurea is labor intensive. Hydroxyurea is a chemotherapeutic agent that requires the same level of nursing and physician oversight as any child with cancer receiving chemotherapy. The parents must be educated about the consequences of therapy, and when ill, children should be promptly evaluated. Complete blood count should be checked at least every 4 wk after initiation of therapy or any dose change to monitor for hematologic toxicity and then every 8 wk.

Hydroxyurea should be temporarily discontinued and dose adjusted if the absolute neutrophil count falls below 2,000/µL or platelets fall below 80,000/µL. Hydroxyurea is a pregnancy class D medication and adolescents should be counseled regarding methods to prevent pregnancy while taking hydroxyurea. Close monitoring of the patient requires a commitment by the parents and patient, as well as diligence by a physician, to identify toxicity early.

Regular Blood Transfusion Therapy

At the initiation of blood transfusion therapy, children with sickle cell anemia should have testing to identify the presence of alloantibodies and red blood cell phenotyping, which is performed to identify the best matched blood. Children meeting criteria for chronic transfusion therapy should receive annual evaluation for transfusion transmitted infections including hepatitis B, hepatitis C, and human immunodeficiency virus (HIV). After receiving 100 mg/kg of red blood cell transfusions, regular assessments of iron overload should begin; usually periodic measurements of serum ferritin. For children requiring chelation therapy, an audiogram should be performed annually, as well as monitoring for organ toxicity, including liver function tests and endocrine evaluation of pituitary dysfunction because of iron deposition.

Pulmonary and Asthma Screening

Pulmonary complications of sickle cell disease are common and life-threatening. Asthma is common particularly in African-American children. As would be the case in all children, good clinical practice necessitates evaluation for asthma symptoms and asthma risk factors in children with sickle cell disease, particularly in light of the insurmountable evidence that asthma is associated with increased rate of sickle cell disease morbidity and mortality. All children should receive annual screening for signs and symptoms of lower airway disease, such as nighttime cough and exercise-induced cough. In children with symptoms consistent with lower airway disease, consider consultation with an asthma specialist. Pulse oximetry readings should be performed during well visits to identify children with abnormally low daytime oxygen saturations. For children with snoring and daytime somnolence, and symptoms associated with obstructive sleep apnea syndrome, referral to a sleep specialist should be considered.

Retinopathy

Effective therapy for retinopathy associated with sickle cell disease exists. Patients at highest risk for the development of retinopathy should receive annual screening by an ophthalmologist to identify vascular changes that would benefit from laser therapy. Although changes may occur earlier, children with sickle cell disease should begin annual screening at age 10 yr.

Renal

Sickle cell–associated renal disease, starts in infancy and may not become clinically manifested until adulthood. Screening for early signs of sickle nephropathy using urinalysis to identify proteinuria is recommended with annual albumin : creatinine ratios. The age to begin screening for proteinuria has not been defined, but some experts recommend screening annually after at least 10 yr of age if not sooner. If the albumin : creatinine ratio is elevated (>30 mg/g), it should be repeated with an early morning urine collection, and if still elevated, the patient should be referred to a pediatric nephrologist. Males with sickle cell disease should also receive counseling regarding the diagnosis and treatment of priapism. Because of the high frequency of enuresis beyond early childhood, approximately 9% of adolescents between 18 and 20 yr of age, parents and caregivers should be educated about the prolonged nature of enuresis in this disease. As is the case in the general population, obstructive sleep apnea syndrome is associated with an increased prevalence of enuresis in sickle cell disease. Unfortunately, no evidence-based therapies have been developed to treat enuresis in children and young adults with sickle cell disease. In children with enuresis who have symptoms and clinical features of obstructive sleep apnea syndrome, referral to sleep specialists for evaluation is recommended.

Echocardiography

Echocardiography has gained popularity as a screening tool to identify individuals with sickle cell disease who have pulmonary artery hypertension. No evidence currently exists that children with sickle cell disease and elevated tricuspid jet velocity above 2.5 cm/sec have an increased rate of mortality. Subsequent studies in adults with sickle cell disease have found the echocardiography to be insensitive at identifying individuals truly at risk for pulmonary hypertension, although an elevated tricuspid velocity measurement may still be a risk factor for premature death in adults with sickle cell disease. The current recommendation is to refer those with severe cardiopulmonary symptoms from associated pulmonary artery hypertension to pediatric cardiologist for a more formal evaluation.

Bibliography is available at Expert Consult.

462.2 Sickle Cell Trait (Hemoglobin AS)

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

The prevalence of sickle cell trait varies throughout the world; in the United States, the incidence is 7-10% of African-Americans. Because all state newborn screening programs include sickle cell disease, for most children, sickle cell trait is first identified on their newborn screen. Communication of sickle cell trait status from infancy to young adulthood for the affected individual, family, and healthcare providers is often inconsistent and many young adults are unaware of their sickle cell trait status.

The production of HbS is influenced by the number of α-thalassemia genes present, and the amount of HbS. By definition among individuals with sickle cell trait, the HbS level is <50%. The life span of people with sickle cell trait is normal, and serious complications are extremely rare. The CBC is within the normal range (Fig. 462-5*B*). Hemoglobin analysis is diagnostic, revealing a predominance of HbA, typically >50%, and HbS <50%. Rare complications of sickle cell trait are associated with sudden death during rigorous exercise, splenic infarction at high altitude, hematuria, hyposthenuria, deep vein thrombosis, and susceptibility to eye injury with formation of a hyphema (Table 462-5). Renal

medullary carcinoma is also associated with sickle cell trait and occurs predominantly in young adults and children.

Children with sickle cell trait do not require limitations on physical activities. Sudden death in persons with sickle cell trait while exercising under extreme conditions is most likely associated with a second genetic factor and/or environmental factors, and not the presence of sickle cell trait itself. No causal pathway has been implicated for the presence of sickle cell trait and sudden death. All patients with sickle cell trait who participate in rigorous athletic activities should receive maximum hydration and appropriate rest during exertion, as would be the precautionary steps for all athletes, particularly when participating in hot humid conditions. The presence of sickle cell trait should never be a reason to exclude a person from athletic participation but rather should serve as an indication that prudent surveillance is necessary to ensure appropriate hydration and prevention of exhaustion from heat or other strenuous exercise. If athletes are to be screened for sickle cell trait, then appropriate genetic counseling should be provided, along with the knowledge that genetic information may provide opportunities to challenge paternity. Such situations are typically handled by a pediatrician or hematologist accustomed to providing both a balanced approach to genetic counseling and addressing the challenges about paternity.

462.3 Other Hemoglobinopathies

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

HEMOGLOBIN C

The mutation for HbC is at the same site as HbS, with substitution of lysine instead of valine for glutamine. In the United States, hemoglobin C trait (HbAC) occurs in 1:40 and homozygous

hemoglobin C disease (HbCC) occurs in 1 : 5,000 African-Americans. HbAC is asymptomatic. HbCC can result in mild anemia, splenomegaly, and cholelithiasis; rare cases of spontaneous splenic rupture have been reported. Sickling does not occur. This condition is usually diagnosed through newborn screening programs. HbC crystallizes, disrupting the red cell membrane, and HbC crystals may be visible on peripheral smear (see Fig. 462-5*C*).

HEMOGLOBIN E

HbE is an abnormal hemoglobin resulting from a qualitative mutation in the β-globin gene and is the second most common globin mutation worldwide. Patients may have asymptomatic hemoglobin E trait (HbAE) or benign homozygous hemoglobin E disease (HbEE). Compound heterozygous hemoglobin E/β-thalassemia produces clinical phenotypes ranging from moderate to severe anemia depending on the β-thalassemia mutation. In California, HbE/β-thalassemia is found almost exclusively in persons of Southeast Asian descent, with a prevalence of 1 : 2,600 births.

HEMOGLOBIN D

At least 16 variants of HbD exist. HbD-Punjab (Los Angeles) is a rare hemoglobin that is seen in 1-3% of Western Indians and in some Europeans with Asian-Indian ancestry and produces symptoms of sickle cell disease when present in combination with HbS. Heterozygous HbD or hemoglobin D trait (HbAD) is clinically silent. Homozygous HbDD or HbD disease produces a mild to moderate anemia with splenomegaly.

462.4 Unstable Hemoglobin Disorders

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

At least 200 rare unstable hemoglobins have been identified; the most common is Hb Köln. Most patients seem to have de novo mutations rather than inherited hemoglobin disorders. The best studied unstable hemoglobins are the ones leading to hemoglobin denaturation from mutations affecting heme binding. The denatured hemoglobin can be visualized during severe hemolysis or after splenectomy as Heinz bodies. Unlike the Heinz bodies seen after toxic exposure, in unstable hemoglobins, Heinz bodies are present in reticulocytes and older red cells (see Fig. 462-5*D*). Heterozygotes are asymptomatic.

Children with homozygous gene mutations can present in early childhood with anemia and splenomegaly or with unexplained hemolytic anemia. Hemolysis is increased with febrile illness and with the ingestion of oxidant medications (similar to glucose-6-phosphate dehydrogenase [G6PD] deficiency) with some unstable hemoglobins. If the spleen is functional, the blood smear can appear almost normal or have only hypochromasia and basophilic stippling. A diagnosis may be made by demonstrating Heinz bodies, hemoglobin instability, or an abnormal hemoglobin analysis (although some unstable hemoglobins have normal mobility and are not detected on hemoglobin analysis).

Treatment is supportive. Transfusion may be required during hemolytic episodes in severe cases. Oxidative drugs should be avoided, and folate supplementation may be helpful if dietary deficiency is a concern. Splenectomy may be considered in patients requiring recurrent transfusion or demonstrating poor growth, but the complications of splenectomy, including bacterial sepsis, risk of thrombosis, and the possibility of developing pulmonary hypertension, should be considered before surgery.

462.5 Abnormal Hemoglobins with Increased Oxygen Affinity

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

More than 110 high-affinity hemoglobins have been characterized. These mutations affect the state of hemoglobin configuration during oxygenation and deoxygenation. Hemoglobin changes structure when in the oxygenated versus the deoxygenated state. The deoxygenated state is termed the T (tense) state and is stabilized by 2,3-diphosphoglycerate. When fully oxygenated, hemoglobin assumes the R (relaxed) state. The exact molecular interactions between these 2 states are unknown. High-affinity hemoglobins contain mutations that either stabilize the R form or destabilize the T form. The interactions between the R and T forms are complex, and the mechanisms of the mutations are not known. In most cases, the high-affinity hemoglobins can be identified by hemoglobin analysis; approximately 20% must be characterized under controlled conditions where measurements are obtained with the P_{50} lowered to 9-21 mm Hg (normal: 23-29 mm Hg). The decreased P_{50} in these hemoglobins leads to an erythrocytosis with hemoglobin levels of 17-20 g/dL. Levels of erythropoietin and 2,3-diphosphoglycerate are normal. Patients are usually asymptomatic and do not need phlebotomy. If phlebotomy is performed, oxygen delivery could be problematic owing to the reduced number of hemoglobin molecules to carry oxygen.

462.6 Abnormal Hemoglobins Causing Cyanosis

Michael R. DeBaun, Allison Grimes, Melissa J. Frei-Jones, and Elliott P. Vichinsky

Abnormal hemoglobins causing cyanosis, also called structural methemoglobinemias, are rare. They are referred to as "M-hemoglobins" and represent a group of hemoglobin variants which result from point mutations in one of the globin chains, α, β, or γ located in the heme pocket. Thirteen known variants exist. These unstable hemoglobins lead to hemolytic anemia, most pronounced when the β-globin gene is affected. Clinically, these children are cyanotic from birth, without other signs or symptoms of disease, if the mutation is in the α-globin gene (HbM Boston, HbM Iwate, Hb Auckland). Infants with β-globin mutations become cyanotic later in infancy after the fetal hemoglobin switch (HbM Saskatoon, HbM Chile, HbM Milwaukee 1 and 2). γ-Chain mutations (HbF-M Fort Ripley, HbF-M Osaka, HbF Cincinnati, HbF Circleville, HbF Toms River, HbF Viseu) are all transient, presenting with cyanosis at birth, which resolves during the neonatal period after HbF production discontinues. The abnormal M hemoglobins exhibit autosomal dominant inheritance and are diagnosed by hemoglobin analysis. HbM variants may be not be isolated reliably using hemoglobin analysis (HPLC or isoelectric focusing [IEF]), consequently diagnostic confirmation may require DNA sequencing or mass spectrometry. There is no specific treatment and affected patients do not respond to treatments used for enzyme-deficient methemoglobinemia. Beyond cyanosis, individuals are otherwise asymptomatic and do not require additional monitoring. Children with the β-globin form should avoid oxidant drugs. Individuals with all forms have a normal life expectancy and pregnancy course.

Low-affinity hemoglobins have less cyanosis than the M hemoglobins. The amino acid substitutions destabilize the oxyhemoglobin and lead to decreased oxygen saturation. The best characterized are Hb Kansas, Hb Beth Israel, and Hb Denver. Hemoglobin analysis (IEF and HPLC techniques) may be normal in affected individuals. When clinically suspected, oxygen affinity studies reveal a right-shifted dissociation curve and heat testing demonstrates unstable hemoglobin. Children present with mild cyanosis only.

462.7 Hereditary Methemoglobinemia

Michael R. DeBaun, Allison Grimes, Melissa J. Frei-Jones, and Elliott P. Vichinsky

Hereditary methemoglobinemia is a clinical syndrome caused by an increase in the serum concentration of methemoglobin either as a result of congenital changes in hemoglobin synthesis or of metabolism

leading to imbalances in reduction and oxidation of hemoglobin. The iron molecule in hemoglobin is normally in the ferrous state (Fe^{2+}), which is essential for oxygen transport. Under physiologic conditions there is a slow, constant loss of electrons to released oxygen, and the ferric (Fe^{3+}) form combines with water, producing methemoglobin (MetHb). The newly formed MetHb has a reduced ability to bind oxygen.

Two pathways for MetHb reduction exist. The physiologic and predominant pathway is a reduced form of nicotinamide adenine dinucleotide (NADH)-dependent reaction catalyzed by cytochrome b5 reductase. This mechanism is >100-fold more efficient than the production of MetHb. The alternate pathway utilizes nicotinamide adenine dinucleotide phosphate generated by G6PD in the hexose monophosphate shunt and requires an extrinsic electron acceptor to be activated (i.e., methylene blue, ascorbic acid, riboflavin). In normal individuals, oxidation of hemoglobin to MetHb occurs at a slow rate, 0.5-3%, which is countered by MetHb reduction to maintain a steady state of 1% MetHb.

MetHb may be increased in the red cell owing to exposure to toxic substances or to absence of reductive pathways, such as NADH-cytochrome b5 reductase deficiency. Toxic methemoglobinemia is much more common than hereditary methemoglobinemia (Table 462-6). Infants are exceptionally vulnerable to hemoglobin oxidation because their erythrocytes have half the amount of cytochrome b5 reductase seen in adults, fetal hemoglobin is more susceptible to oxidation than hemoglobin A, and the more alkaline infant gastrointestinal tract promotes the growth of nitrite-producing Gram-negative bacteria. When MetHb levels are >1.5 g/24 hr, cyanosis is visible (15% MetHb); a level of 70% MetHb is lethal. The MetHb level is usually reported as a percentage of normal hemoglobin, and the toxic level is lower at a lower hemoglobin level. Methemoglobinemia has been described in infants who ingested foods and water high in nitrates, who were exposed to aniline teething gels or other chemicals, and in some infants with severe gastroenteritis and acidosis. Methemoglobin can color the blood brown (Fig. 462-6).

462.8 Hereditary Methemoglobinemia with Deficiency of NADH Cytochrome b5 Reductase

Michael R. DeBaun, Allison Grimes, Melissa J. Frei-Jones, and Elliott P. Vichinsky

The first reported inherited disorder causing methemoglobinemia resulted from an enzymatic deficiency of NADH cytochrome b5 reductase, which was classified into 2 distinct phenotypes. In type I, the most common form, the deficiency of NADH cytochrome b5 activity is found only in erythrocytes, with other cell types unaffected. In type II, the enzyme deficiency is present in all tissues and results in more significant symptoms beginning in infancy with encephalopathy, mental retardation, spasticity, microcephaly, and growth retardation with death most often by 2 yr of age. Both types exhibit an autosomal recessive inheritance pattern.

Clinically, cyanosis varies in intensity with season and diet. The time of cyanosis onset also varies; in some patients it appears at birth, in others as late as adolescence. Although as much as 50% of the total circulating hemoglobin may be in the form of nonfunctional MetHb, little or no cardiorespiratory distress occurs in these patients, except on exertion.

Daily oral treatment with ascorbic acid (200-500 mg/day in divided doses) gradually reduces the MetHb to approximately 10% of the total

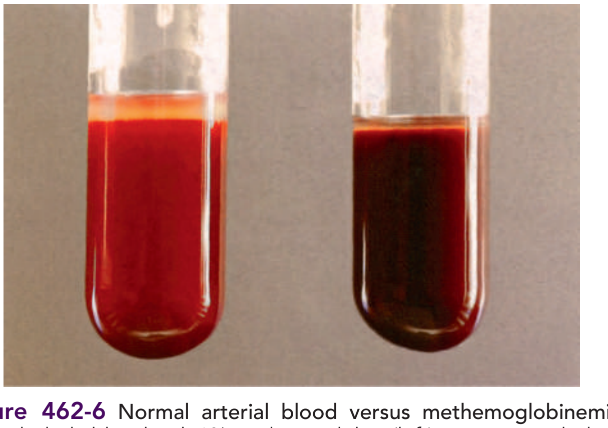

Figure 462-6 Normal arterial blood versus methemoglobinemia. Arterial whole blood with 1% methemoglobin *(left)* versus arterial whole blood with 72% methemoglobin *(right)*. Note the characteristic chocolate-brown color of the sample with an elevated methemoglobin level. Both samples were briefly exposed to 100% oxygen and shaken. This quick analysis is a good bedside test for methemoglobinemia. The sample on the *left* turned bright red, whereas the sample on the *right* remained chocolate-brown. Methods: Whole blood samples were drawn at the same time from the same person. The measured hemoglobin concentration was 11.7 g/dL. Calculated concentration of methemoglobin: 11.7 g/dL × 0.01 = 0.117 g/dL *(left)* and 11.7 g/dL × 0.72 = 8.42 g/dL *(right)*. An elevated methemoglobin level was made in vitro by adding 0.1 mL of a 0.144 molar solution of sodium nitrate *(right)*, and 0.1 mL of normal saline was added as a control *(left)*. Cooximetry measurements were taken on both samples shortly after the blood was drawn and 20 min after the addition of sodium nitrate solution. Both blood samples were exposed to 100% oxygen before the second measurement. *(Protocol based on personal communication with Dr. Ali Mansouri, December 2002.)*

pigment and alleviates the cyanosis as long as therapy is continued. Chronic high doses of ascorbic acid have been associated with hyperoxaluria and renal stone formation. Ascorbic acid should not be used to treat toxic methemoglobinemia. When immediately available, poison control should be contacted to verify the most up-to-date therapeutic strategies. Like ascorbic acid, riboflavin utilizes the alternate pathway of MetHb reduction and is most effective when given in high doses (400 mg once daily). Methylene blue, administered intravenously (1-2 mg/kg initially), is used to treat toxic methemoglobinemia. An oral dose can be administered (100-300 mg PO per day) as maintenance therapy.

Methylene blue should not be used in patients with G6PD deficiency. This treatment is ineffective and can cause severe oxidative hemolysis. In the event that methylene blue is given to a patient with G6PD deficiency, there will be no improvement in symptoms and marked hemolysis has been reported within 24 hr of administration. Because G6PD deficiency status is rarely known at the time of treatment, a careful history should be elicited. When the history is negative for symptoms of G6PD deficiency, treatment with methylene blue should be initiated judiciously, and the patient should be closely monitored for improvement.

462.9 Syndromes of Hereditary Persistence of Fetal Hemoglobin

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

HPFH syndromes are a form of thalassemia; mutations are associated with a decrease in the production of either or both β- and δ-globins. There is an imbalance in the α:non-α synthetic ratio (see Chapter 462.9) characteristic of thalassemia. More than 20 variants of HPFH have been described. They are deletional, $\delta\beta^0$ (Black, Ghanaian, Italian), nondeletional (Tunisian, Japanese, Australian), linked to the β-globin–gene cluster (British, Italian-Chinese, Black), or unlinked to the β-globin–gene cluster (Atlanta, Czech, Seattle). The $\delta\beta^0$ forms have deletions of the entire δ- and β-globin gene sequences, and the most common form in the United States is the Black (HPFH 1) variant. As a result of the δ and β gene deletions, there is production only of γ-globin and formation of HbF. In the homozygous form, no manifestations of thalassemia are present. There is only HbF with very mild anemia and slight microcytosis. When inherited with other variant hemoglobins, HbF is elevated into the 20-30% range; when inherited with HbS, there is an amelioration of sickle cell disease with fewer complications.

462.10 Thalassemia Syndromes

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

Thalassemia refers to a group of genetic disorders of globin chain production in which there is an imbalance between the α-globin and β-globin chain production. β-Thalassemia syndromes result from a decrease in β-globin chains, which results in a relative excess of α-globin chains. β^0-Thalassemia refers to the absence of production of the β-globin. When patients are homozygous for the β-thalassemia gene, they cannot make any normal β chains (HbA). β^+-Thalassemia indicates a mutation that makes decreased amounts of normal β-globin, but it is still present (HbA). β^0-Thalassemia syndromes are more severe than β^+-thalassemia syndromes, but there is significant variability between the genotype and phenotype. β-Thalassemia major refers to the severe β-thalassemia patient who requires early transfusion therapy and often is homozygous for β^0 mutations. β-Thalassemia intermedia is a clinical diagnosis of a patient with a less-severe clinical phenotype that usually does not require transfusion therapy in childhood. Many of these patients have at least 1 β^+-thalassemia mutation. β-Thalassemia syndromes usually require a β-thalassemia mutation in both β-globin genes. Carriers with a single β-globin mutation are generally asymptomatic, except for microcytosis and mild anemia. In α-thalassemia, there is an absence or reduction in α-globin production. Normal individuals have 4 α-globin genes. The more genes affected, the more severe the disease. An α^0-mutation indicates no α-chains produced from that gene. An α^+ mutation produces a decreased amount of α-globin chain. The primary pathology in the thalassemia syndromes stems from the quantity of globin produced, whereas the primary pathology in sickle cell disease is related to the quality of β-globin produced.

EPIDEMIOLOGY

There are >200 different mutations resulting in absent or decreased globin production. Although most are rare, the 20 most common abnormal alleles constitute 80% of the known thalassemias worldwide; 3% of the world's population carries alleles for β-thalassemia, and in Southeast Asia 5-10% of the population carry alleles for α-thalassemia. In a particular region, there are fewer common alleles. In the United States, an estimated 2,000 persons have β-thalassemia major.

PATHOPHYSIOLOGY

Two related features contribute to the sequelae of β-thalassemia major: inadequate β-globin gene production leading to decreased levels of normal hemoglobin (HbA) and unbalanced α- and β-globin chain production. In β-thalassemia major, α-globin chains are in excess to non–α-globin chains, and α-globin tetramers (α_4) are formed and appear as red cell inclusions. The free α-globin chains and inclusions are very unstable, precipitate in red cell precursors, damage the red cell membrane, and shorten red cell survival leading to anemia and increased erythroid production. Table 462-7 shows selected features of thalassemia. This results in a marked increase in erythropoiesis with early erythroid precursor death in the bone marrow. Clinically, this is characterized by a lack of maturation of erythrocytes and an inappropriately low reticulocyte count. This ineffective erythropoiesis and the compensatory massive marrow expansion with erythroid hyperactivity characterize β-thalassemia. Because the β^0-thalassemia patient cannot make HbA, the α-chains combine with γ-chains, resulting in HbF ($\alpha_2\gamma_2$) being the dominant hemoglobin. In addition to the natural survival effect, the γ-globin chains may be produced in increased amounts, which is regulated by genetic polymorphisms. δ-Chain synthesis is not usually affected in β-thalassemia or β-thalassemia trait, and, therefore, patients have a relative or absolute increase in HbA_2 production ($\alpha_2\delta_2$).

In the α-thalassemia syndromes, 2 genes with 2 maternal and 2 paternal alleles control α-globin production, which varies from complete absence (hydrops fetalis) to only slightly reduced (α-thalassemia silent carrier). In the α-thalassemia syndromes, an excess of β- and γ-globin chains are produced. These excess chains form Bart hemoglobin (γ_4) in fetal life and HbH (β_4) after birth. These abnormal tetramers are nonfunctional hemoglobins with very high oxygen affinity. They do not transport oxygen and result in extravascular hemolysis. A fetus with the most severe form of α-thalassemia (hydrops fetalis) develops in utero anemia and fetal loss because HbF production requires sufficient amounts of α-globin. In contrast, infants with β-thalassemia major become symptomatic only after birth when HbA predominates and insufficient β-globin production manifests in clinical symptoms.

HOMOZYGOUS β-THALASSEMIA (THALASSEMIA MAJOR, COOLEY ANEMIA)

Clinical Manifestations

If not treated, children with homozygous β^0-thalassemia usually become symptomatic from progressive hemolytic anemia, with profound weakness and cardiac decompensation during the 2nd 6 mo of life. Depending on the mutation and degree of fetal hemoglobin production, transfusions in β-thalassemia major are necessary beginning in the 2nd mo to 2nd yr of life, but rarely later. The decision to transfuse is multifactorial but is not determined solely by the degree of anemia. The developing signs of ineffective erythropoiesis such as growth

Table 462-7 The Thalassemias

THALASSEMIA	GLOBIN GENOTYPE	FEATURES	EXPRESSION	HEMOGLOBIN ANALYSIS
α-THALASSEMIA				
1 Gene allele deletion	$-,\alpha/\alpha,\alpha$	Normal	Normal	Newborn: Bart 1-2%
2 Gene allele deletion trait	$-,\alpha/-,\alpha$ $-$, $-/\alpha,\alpha$	Microcytosis, mild hypochromasia	Normal, mild anemia	Newborn: Bart: 5-10%
3 Gene allele deletion hemoglobin H	$-,-/-,\alpha$	Microcytosis, hypochromic	Mild anemia, transfusions not required	Newborn: Bart: 20-30%
2 Gene allele deletion + Constant Spring	$-,-/\alpha,\alpha^{Constant\ Spring}$	Microcytosis, hypochromic	Moderate to severe anemia, transfusion, splenectomy.	2-3% Constant Spring, 10-15% HbH
4 Gene allele deletion	$-,-/-,-$	Anisocytosis, poikilocytosis	Hydrops fetalis	Newborn: 89-90% Bart with Gower 1 and 2 and Portland
Nondeletional	$\alpha,\alpha/\alpha,\alpha^{variant}$	Microcytosis, mild anemia	Normal	1-2% variant hemoglobin
β-THALASSEMIA				
β^0 or β^+ heterozygote: trait	$\beta^0/A, \beta^+/A$	Variable microcytosis	Normal	Elevated A_2, variable elevation of F
β^0-Thalassemia	β^0/β^0, β^+/β^0, E/β^0	Microcytosis, nucleated RBC	Transfusion dependent	F 98% and A_2 2%, E 30-40%
β^+-Thalassemia severe	β^+/β^+	Microcytosis nucleated RBC	Transfusion dependent/ thalassemia intermedia	F 70-95%, A_2 2%, trace A
Silent	β^+/A	Microcytosis	Normal with only microcytosis	A_2 3.3-3.5%
β^+/β^+	Hypochromic, microcytosis	Mild to moderate anemia	A_2 2-5%, F 10-30%	
Dominant (rare)	B^0/A	Microcytosis, abnormal RBCs	Moderately severe anemia, splenomegaly	Elevated F and A_2
δ-Thalassemia	A/A	Normal	Normal	A_2 absent
$(\delta\beta)^0$-Thalassemia	$(\delta\beta)^0/A$	Hypochromic	Mild anemia	F 5-20%
$(\delta\beta)^+$-Thalassemia Lepore	β^{Lepore}/A	Microcytosis	Mild anemia	Lepore 8-20%
Lepore	$\beta^{Lepore}/\beta^{Lepore}$	Microcytic, hypochromic	Thalassemia intermedia	F 80%, Lepore 20%
γδβ-Thalassemia	$(\gamma^A\delta\beta)^0/A$	Microcytosis, microcytic, hypochromic	Moderate anemia, splenomegaly, homozygote: thalassemia intermedia	Decreased F and A2 compared with δβ-thalassemia
γ-Thalassemia	$(\gamma^A\gamma^G)^0/A$	Microcytosis	Insignificant unless homozygote	Decreased F
HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN				
Deletional	A/A	Microcytic	Mild anemia	F 100% homozygotes
Nondeletional	A/A	Normal	Normal	F 20-40%

failure, bone deformities secondary to marrow expansion, hepatosplenomegaly are important variables in determining transfusion initiation.

The classic presentation of children with severe disease includes thalassemic facies (maxilla hyperplasia, flat nasal bridge, frontal bossing), pathologic bone fractures, marked hepatosplenomegaly, and cachexia and is now primarily seen in countries without access to chronic transfusion therapy. Occasionally, patients with moderate anemia develop these features because of severe compensatory ineffective erythropoiesis.

In nontransfused patients with severe ineffective erythropoiesis, marked splenomegaly can develop with hypersplenism and abdominal symptoms. The features of ineffective erythropoiesis include expanded medullary spaces (with massive expansion of the marrow of the face and skull producing the characteristic thalassemic facies), extramedullary hematopoiesis, and higher metabolic needs (Fig. 462-7). The chronic anemia without transfusion exposure produces an increase in iron absorption from the gastrointestinal tract and secondary hemosiderosis-induced organ injury.

Chronic transfusion therapy dramatically improves the quality of life and reduces the complications of severe thalassemia. Transfusion-induced hemosiderosis becomes the major clinical complication of transfusion-dependent thalassemia. Each mL of packed red cells contains 1 mg of iron. Physiologically, there is no mechanism to eliminate excess body iron. Iron is initially deposited in the liver. Liver hemosiderosis develops after 1 yr of chronic transfusion therapy and is followed by iron deposition in the endocrine system. This leads to a high rate of hypothyroidism, hypogonadotrophic gonadism, growth hormone deficiency, hypoparathyroidism, and diabetes mellitus. After 10 yr of transfusion, cardiac dysfunction secondary to hemosiderosis begins. Eventually, most patients not receiving adequate iron chelation therapy die from cardiac failure and/or cardiac arrhythmias secondary to hemosiderosis. Hemosiderosis induced morbidity can be prevented by adequate iron chelation therapy.

Laboratory Findings

In the United States, some children with β-thalassemia major will be identified on newborn screening as a result of the detection of only HbF on hemoglobin electrophoresis. However, the ethnicity and the mutations associated with transfusion-dependent thalassemia in United States have dramatically changed. Many of the patients have diverse mutations, such as HbE thalassemia, which may not be identified or followed up by a newborn screening program. HbFE in the newborn may be a very common benign mutation caused by homozygous HbEE or an uncommon severe HbE β^0-thalassemia. The lack of standardized neonatal diagnosis of thalassemia disorders requires close follow-up of newborns with unclear thalassemia mutations and/or babies from high-risk ethnic groups.

Infants with serious β-thalassemia disorders have a progressive anemia after the newborn period. Microcytosis (MCV), hypochromia (MCH), and targeting characterize the red cells. Nucleated red cells, marked anisopoikilocytosis, and a relative reticulocytopenia are typically seen (see Fig. 462-5*E*). The hemoglobin level falls progressively to <6 g/dL unless transfusions are given. The reticulocyte count is

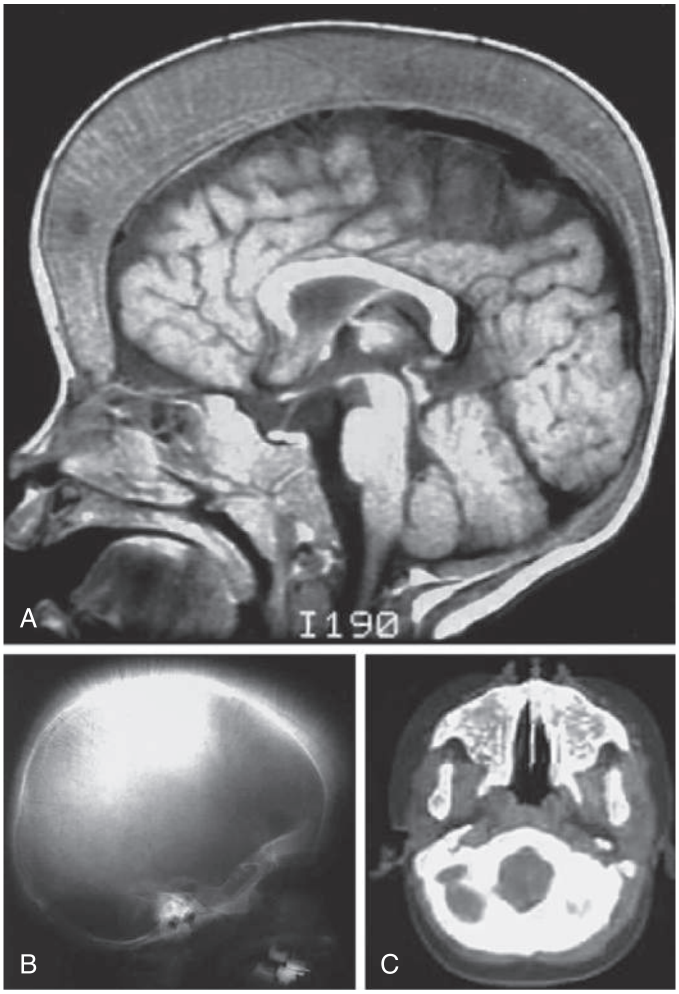

Figure 462-7 Ineffective erythropoiesis in a 3 yr old patient who has β-thalassemia major and has not received a transfusion. **A,** Massive widening of the diploic spaces of the skull as seen on MRI. **B**, Radiographic appearance of the trabeculae as seen on plain radiograph. **C,** Obliteration of the maxillary sinuses with hematopoietic tissue as seen on CT scan.

commonly <8% and is inappropriately low when compared to the degree of anemia as a result of ineffective erythropoiesis. The unconjugated serum bilirubin level is usually elevated, but other chemistries may be normal early on. Even if the child does not receive transfusions, iron eventually accumulates with elevated serum ferritin and transferrin saturation. Bone marrow hyperplasia can be seen on radiographs (see Fig. 462-7).

Early definitive diagnosis is recommended. Newborn screening techniques such as hemoglobin electrophoresis is not definitive. DNA diagnosis of the β-thalassemia mutation, along with testing for common genetic modifiers of the clinical phenotype, is recommended. Coinheritance of an α-thalassemia mutation is common, and it decreases the severity of the β-thalassemia disease. Some patients' mutations cannot be diagnosed by standard electrophoresis or common DNA probes. Referral of the samples to a tertiary laboratory along with parental and family testing are indicated. Following the definitive diagnosis, families should undergo detailed counseling.

Management and Treatment of Thalassemia

Transfusion Therapy

Before initiating chronic transfusions, the diagnosis of transfusion dependent β-thalassemia should be confirmed by both clinical and laboratory parameters. β-Thalassemia major is a clinical diagnosis that requires the integration of laboratory findings and the clinical course. Of patients with homozygous β^0-thalassemia (the most severe mutations), 15-20% may have a clinical course that is phenotypically consistent with thalassemia intermedia. In contrast, 25% of patients with homozygous β^+-thalassemia, typically a more benign genotype, may become transfusion-dependent thalassemia major. Transient clinical events, such as a sudden fall in hemoglobin secondary to an episode of parvovirus requiring transfusion, do not necessarily indicate the patient is a transfusion-dependent patient. The long-term observation of the clinical characteristics, such as growth, bony changes, and hemoglobin, are necessary to determine chronic transfusion therapy.

Guidelines for Transfusion Therapy. Patients at risk for transfusion therapy should have an extended red cell phenotype and/or genotype. Patients should receive red cells depleted of leukocytes and matched for, at least, D, C, c, E, e, and Kell antigens. Cytomegalovirus-negative units are indicated in stem cell transplantation candidates. Transfusions should generally be given at intervals of 3-4 wk, with the goal being to maintain a pretransfusion hemoglobin level of 9.5-10.5 g/dL. Ongoing monitoring for transfusion-associated transmitted infections (hepatitis A, hepatitis B, hepatitis C, HIV), alloimmunization, annual blood transfusion requirements, and transfusion reactions is essential.

Iron Overload Monitoring

Excessive iron stores from transfusion cause many of the complications of β-thalassemia major. Accurate assessment of excessive iron stores is essential to optimal therapy. Serial serum ferritin levels are a useful screening technique in assessing iron balance trends, but results may not accurately predict quantitative iron stores. Undertreatment or overtreatment of presumed excessive iron stores can occur in managing a patient based on serum ferritin alone. Noninvasive measurement of quantitative organ injury is rapidly improving the treatment of iron overload. Quantitative measurement of liver iron and cardiac iron are standard and measurement of pancreatic and gonadal iron may be available soon. This technology, in collaboration with access to multiple chelators, will enable targeted chelation therapy for patients with organ specific hemosiderosis before the onset of overt organ failure. Available data suggests integration of these imaging technologies with chelation therapy may prevent heart failure, diabetes, and other pending organ dysfunction.

Quantitative liver iron by approved MRI technology is the best indicator of total-body iron stores and should be obtained in chronically transfused patients after chronic transfusion therapy has initiated. The liver iron results will help guide the chelation regimen.. Quantitative cardiac iron, determined by T2* MRI cardiac software, should be obtained after 7 yr of transfusion therapy. It is not uncommon to have a discrepancy between the liver iron and the heart iron because of different rates of tissue loading and cardiac chelation efficacy.

Chelation Therapy

Iron-chelation therapy should start as soon as the patient becomes significantly iron overloaded. In general, this occurs after 1 yr of transfusion therapy and correlates with the serum ferritin >1,000 ng/mL and/or a liver iron concentration of >2,500 μg/g dry weight.

There are 3 available iron chelators (deferoxamine, deferasirox, and deferiprone); each varies in its route of administration, pharmacokinetics, adverse events, and efficacy. Many patients require combination chelation therapy at various points in their illness. The overall goal is to prevent hemosiderosis-induced tissue injury and avoid chelation toxicity. This requires close monitoring of the patients. In general, chelation toxicity increases as iron stores decrease.

Deferoxamine (Desferal) is the most studied iron chelator; it has an excellent safety and efficacy profile. It requires subcutaneous, or intravenous, administration because of a half-life of less than 30 min, necessitating administration of at least 8 hr daily, 5-7 days/wk. Deferoxamine is initially started at 20 mg/kg and can be increased to 60 mg/kg in heavily iron-overloaded patients. The major problem with deferoxamine is noncompliance because of the route of administration.

Adverse side effects include ototoxicity, retinal changes, and bone dysplasia with truncal shortening.

The oral iron chelator deferasirox (Exjade) is commercially available in the United States. Of patients on Desferal, 70% have switched to deferasirox because it is orally available. Deferasirox has a half-life of more than 16 hr and requires once-a-day administration of a dispersible tablet in water. Initial dose is 20 mg/kg with gradual escalation to 30 mg/kg. The most common side effects are gastrointestinal symptoms. The most serious side effect of deferasirox is potential kidney damage. Up to 30% of patients have transient increases in creatinine that requires temporary modifications of dosing. All patients require monthly chemistry panels and ongoing monitoring for proteinuria. Long-term studies in thousands of patients have not demonstrated progressive renal dysfunction, but isolated cases of renal failure in patients have occurred.

Deferiprone (Ferriprox), an oral iron chelator previously only available in Europe, is approved in the United States. Deferiprone has a half-life of approximately 3 hr and requires 25 mg/kg 3 times a day. Deferiprone, a small molecule, effectively enters cardiac tissue and may be more effective than other chelators in reducing cardiac hemosiderosis. The most serious side effect of deferiprone is transient agranulocytosis, which occurs in 1% of patients. It is associated with rare deaths where patients were not adequately monitored. The use of deferiprone requires weekly white blood cell counts.

As thalassemia patients are living longer, the iron-chelation goals have changed. Aggressive treatment with combination chelation therapy is often used in heavily iron-overloaded patients to prevent or reverse organ dysfunction. Deferoxamine, in combination with deferiprone, is routinely used in patients with increased cardiac iron. Combination therapy of deferoxamine and deferasirox may also be efficacious in similar patients.

Hydroxyurea

Hydroxyurea, a DNA antimetabolite, increases stress erythropoiesis, which results in increased HbF production. It has been most successfully used in sickle cell disease and in some patients with β-thalassemia intermedia. Studies in β-thalassemia major are limited. In many parts of the world, hydroxyurea therapy is used in thalassemia intermedia patients. Even though increases in HbF levels are observed, they do not predictively correlate with increase in total hemoglobin in these patients. In general, there appears to be a mean increase in hemoglobin of 1 g (range: 0.1-2.5 g). Hydroxyurea therapy in thalassemia intermedia may have other benefits including decreasing the vascular disease associated with thalassemia intermedia. The initial starting dose for thalassemia intermedia is 10 mg/kg and because these patients are more sensitive to toxicity than sickle cell disease, higher doses are used with great caution.

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation has cured >3,000 patients who had β-thalassemia major. In low-risk HLA-matched sibling patients, there is at least a 90% survival and an 80% event-free survival. In general, myeloablative conditioning regimens are required in order to prevent graft rejection and thalassemia recurrence. Most success has been in children younger than 15 yr of age without excessive iron stores and hepatomegaly who undergo sibling HLA-matched allogeneic transplantation. All children who have an HLA-matched sibling should be offered the option of bone marrow transplantation. Alternative transplantation regimens for patients without donors are experimental and have variable success.

Splenectomy

Surgical Asplenia

Splenectomy may be required in thalassemia patients who develop hypersplenism. These patients have a falling steady state hemoglobin and/or a rising transfusion requirement. Overall, splenectomy is less frequently used as a therapeutic option. There is an increased recognition of serious adverse effects of splenectomy beyond infection risk. In thalassemia intermedia, splenectomized patients have a marked increased risk of venous thrombosis, pulmonary hypertension, leg ulcers, and silent cerebral infarction compared to nonsplenectomized patients. All patients should be fully immunized against encapsulated bacteria and should be on long-term penicillin prophylaxis with appropriate instructions regarding fever management. Prophylactic penicillin should be administered postsplenectomy to prevent sepsis, and families need to be educated on the risk of fever and sepsis.

Preventative Monitoring of Thalassemia Patients

Cardiac. Cardiac disease is the major cause of death in thalassemia. Serial echocardiograms should be monitored to evaluate cardiac function and pulmonary artery pressure. Pulmonary hypertension frequently occurs in non-transfused thalassemia patients and may be an indication for transfusion therapy. After 8 yr of chronic transfusion therapy, cardiac hemosiderosis may occur; consequently, cardiac T2* MRI imaging studies are recommended. Patients with cardiac hemosiderosis and decreasing cardiac ejection fraction require intensive combination chelation therapy.

Endocrine. Endocrine function progressively declines with age secondary to hemosiderosis and nutritional deficiencies. Iron deposition in the pituitary and endocrine organs can result in multiple endocrinopathies, including hypothyroidism, growth hormone deficiency, delayed puberty, and hypoparathyroidism, diabetes mellitus, osteoporosis, and adrenal insufficiency. Monitoring for endocrine dysfunction starts early, around 5 yr of age, or after at least 3 yr of chronic transfusions. All children require monitoring of their height, weight, and sitting height semi-annually. Nutritional assessments are required. Most patients need vitamin D, calcium, vitamin B, vitamin C, and zinc replacement. Fertility is a growing concern among patients and should be assessed routinely.

Psychosocial Support. Thalassemia imposes major disruption in the family unit and significant obstacles to normal development. Culturally sensitive anticipatory counseling is necessary, and the early use of child life services decreases psychological trauma of therapy. Early social service consultation to address financial and social issues is mandatory.

OTHER β-THALASSEMIA SYNDROMES

Nontransfusion-Dependent Thalassemia: β-Thalassemia Intermedia

The β-thalassemia syndromes are characterized by decreased production of β-globin chains of HbA. There are 200-300 β-thalassemia alleles that have now been characterized. These mutations can affect any step in the transcription of β-globin genes. As discussed, β^0-thalassemia is absent production of normal β-chains, and production of β^+ is decreased. Some β-thalassemia mutations have structural mutations such as HbE. Others, such as δβ-thalassemia or HPFH, are variants of β-thalassemia that have decreased production of β-globin gene with increased compensation of HbF. Because phenotypic correlation with genotype is variable, β-thalassemia patients are largely classified by their clinical spectrum. Transfusion-dependent thalassemia, or thalassemia major, is the most severe group. Nontransfusion-dependent thalassemia intermedia include a spectrum of patients who initially are not chronically transfused in infancy but may be sporadically transfused throughout their lifetime. The major determining characteristic of these patients is less α–β-globin chain imbalance than observed in thalassemia major. Sometimes, genetic modifiers alter the primary mutation severity and improve the globin chain imbalance. Coinheritance of α-thalassemia trait or polymorphisms of globin promoters such as BCL11 may convert a thalassemia major patient to a nontransfusion-dependent thalassemia intermedia patient. HbEβ-thalassemia is a common cause of both transfusion-dependent and nontransfusion-dependent thalassemia. These secondary genetic modifiers play a role in altering the severity of this disorder. Occasionally, patients with a single β-thalassemia mutation or autosomal dominant β-thalassemia trait have clinical features of thalassemia intermedia, or nontransfusion-dependent thalassemia. Genetic studies of these patients often uncover a coinheritance of genetic modifiers that worsen the condition such as α-gene triplication or an unstable β-globin mutation.

Thalassemia intermedia patients have significant ineffective erythropoiesis that leads to microcytic anemia with hemoglobin of approximately 7 g/dL (range: 6-10 g/dL). These patients have some of the complications characterized in untransfused thalassemia major patients, but the severity varies depending on the degree of ineffective erythropoiesis. They can develop medullary hyperplasia, hepatosplenomegaly, hematopoietic pseudotumors, pulmonary hypertension, thrombotic events, and growth failure. Many patients develop hemosiderosis secondary to increased gastrointestinal absorption of iron requiring chelation. Extramedullary hematopoiesis can occur in the vertebral canal, compressing the spinal cord and causing neurologic symptoms; the latter is a medical emergency requiring immediate local radiation therapy to halt erythropoiesis. Transfusions are indicated in thalassemia intermedia patients with significant clinical morbidity.

Thalassemia trait is often misdiagnosed as iron deficiency in children because the two produce similar hematologic abnormalities on CBC, and iron deficiency is much more prevalent. A short course of iron and reevaluation is all that is required to identify children who will need further evaluation. Children who have β-thalassemia trait have a persistently normal red cell distribution width and low mean corpuscular volume (MCV), whereas patients with iron deficiency develop an elevated red cell distribution width with treatment. On hemoglobin analysis, they have an elevated HbF and usually increased levels of HbA_2. There are "silent" forms of β-thalassemia trait, and if the family history is suggestive, further studies may be indicated.

α-THALASSEMIA SYNDROMES

The same evolutionary pressures that produced β-thalassemia and sickle cell disease produced α-thalassemia. Infants are identified in the newborn period by the increased production of Bart hemoglobin (γ_4) during fetal life and its presence at birth. The α-thalassemia syndromes occur most commonly in Southeast Asia. Deletion mutations are common in α-thalassemia. In addition to deletional mutations, there are nondeletional α-globin gene mutations, the most common being Constant Spring ($\alpha^{CS}\alpha$); these mutations cause a more severe anemia and clinical course than the deletional mutations. There are 4 α-globin gene alleles and 4 deletional α-thalassemia phenotypes. The different phenotypes in α-thalassemia largely result from whether one (α^+-thalassemia) or both (α^o-thalassemia) α-globin genes are deleted in each of the 2 loci.

The deletion of 1 α-globin gene allele (silent trait) is not identifiable hematologically. Specifically, no alterations are noted in the MCV and mean corpuscular hemoglobin. Persons with this deletion are usually diagnosed after the birth of a child with a 2-gene deletion or HbH (β_4), but some newborn screening programs report even low concentrations of Hb Bart. During the newborn period, <3% Hb Bart is observed. The deletion of 1 α-globin gene allele is common in African-Americans.

The deletion of 2 α-globin gene alleles results in α-thalassemia trait. The α-globin alleles can be lost in a *trans*-(−α/−α) or *cis*- ($\alpha,\alpha/^{-SEA}$) configuration. The *trans* or *cis* mutations can combine with other mutations and lead to HbH or α-thalassemia major. In persons from Africa or of African descent, the most common α-globin deletions are in the *trans* configuration; whereas, in persons from or descended from Asia or the Mediterranean region, *cis* deletions are most common.

α-Thalassemia trait manifest as a microcytic anemia that can be mistaken for iron-deficiency anemia (see Fig. 462-5*F*). The hemoglobin analysis is normal, except during the newborn period, when Hb Bart is commonly <8% but >3%. Children with a deletion of 2 α-globin alleles are commonly thought to have iron deficiency, given the presence of both low MCV and mean corpuscular hemoglobin. The simplest approach to distinguish between iron deficiency and α-thalassemia trait is with a good dietary history. Children with iron-deficiency anemia often have a diet that is low in iron and drink significant amount of cow's milk. Alternatively, a brief course of iron supplementation along with monitoring of erythrocyte parameters might confirm the diagnosis of iron deficiency. If both parents of a child diagnosed with α-thalassemia trait are carriers, they are at risk for a future hydrops fetalis pregnancy. Thus, family screening and genetic counseling are indicated.

The deletion of 3 α-globin gene alleles leads to the diagnosis of HbH disease. A more severe form of HbH disease may be caused by a nondeletional α-globin mutation with 2 allele deletions. HbH Constant Spring ($-\alpha/\alpha,\alpha^{CS}$) is the most common type of nondeletional HbH disease.

In California, where a large population of persons of Asian descent resides, approximately 1 : 10,000 of all newborns have HbH disease. The simplest manner of diagnosing HbH disease is during the newborn period, when excess in γ-tetramers are present and Hb Bart is commonly >25%. Obtaining supporting evidence from the parents is also necessary. Later in childhood, there is an excess of β-globin chain tetramers that results in HbH. A definitive diagnosis of HbH disease requires DNA analysis with supporting evidence. Brilliant cresyl blue can stain HbH, but it is rarely used for diagnosis. Patients with HbH disease have a marked microcytosis, anemia, mild splenomegaly, and, occasionally, scleral icterus or cholelithiasis. Chronic transfusion is not commonly required for therapy because the range of hemoglobin is 7-11 g/dL, with MCV 51-73 fL but intermittent transfusions for worsening anemia may be needed.

The deletion of all 4 α-globin gene alleles causes profound anemia during fetal life, resulting in hydrops fetalis; the ζ-globin gene must be present for fetal survival. There are no normal hemoglobins present at birth (primarily Hb Bart, with Hb Gower 1, Gower 2, and Portland). If the fetus survives, immediate exchange transfusion is indicated. These infants with severe α-thalassemia are transfusion dependent, and hematopoietic stem cell transplantation is the only cure.

Treatment of HbH disease requires ongoing monitoring of growth and organ dysfunction. Dietary supplement with folate and multivitamins without iron is indicated. Older patients may develop decreased bone density with calcium and vitamin D deficiency. Iron supplementation should be avoided. Intermittent transfusion requirements during child development and infection may occur, particularly in nondeletional HbH. Splenectomy is occasionally indicated and because of the high risk of postsplenectomy thrombosis, aspirin or other anticoagulant therapy following splenectomy should be considered. Hemosiderosis, secondary to gastrointestinal iron absorption and/or transfusion exposure, may develop in older patients and require therapy. Because HbH is an unstable hemoglobin sensitive to oxidative injury, oxidative medications should be avoided. At-risk couples for hydrops fetalis should be identified and offered molecular diagnosis on fetal tissue obtained early in pregnancy. Later in pregnancy, intrauterine transfusion can improve fetal survival, but chronic transfusion therapy or bone marrow transplantation for survivors will be required.

Chapter 463
Enzymatic Defects

463.1 Pyruvate Kinase Deficiency

George B. Segel

Congenital hemolytic anemia occurs in persons homozygous or compound heterozygous for autosomal recessive genes that cause either a marked reduction in red blood cell (RBC) pyruvate kinase (PK) or production of an abnormal enzyme with decreased activity resulting in impaired conversion of phosphoenolpyruvate to pyruvate. Generation of adenosine triphosphate (ATP) within RBCs at this step is impaired, and low levels of ATP, pyruvate, and the oxidized form

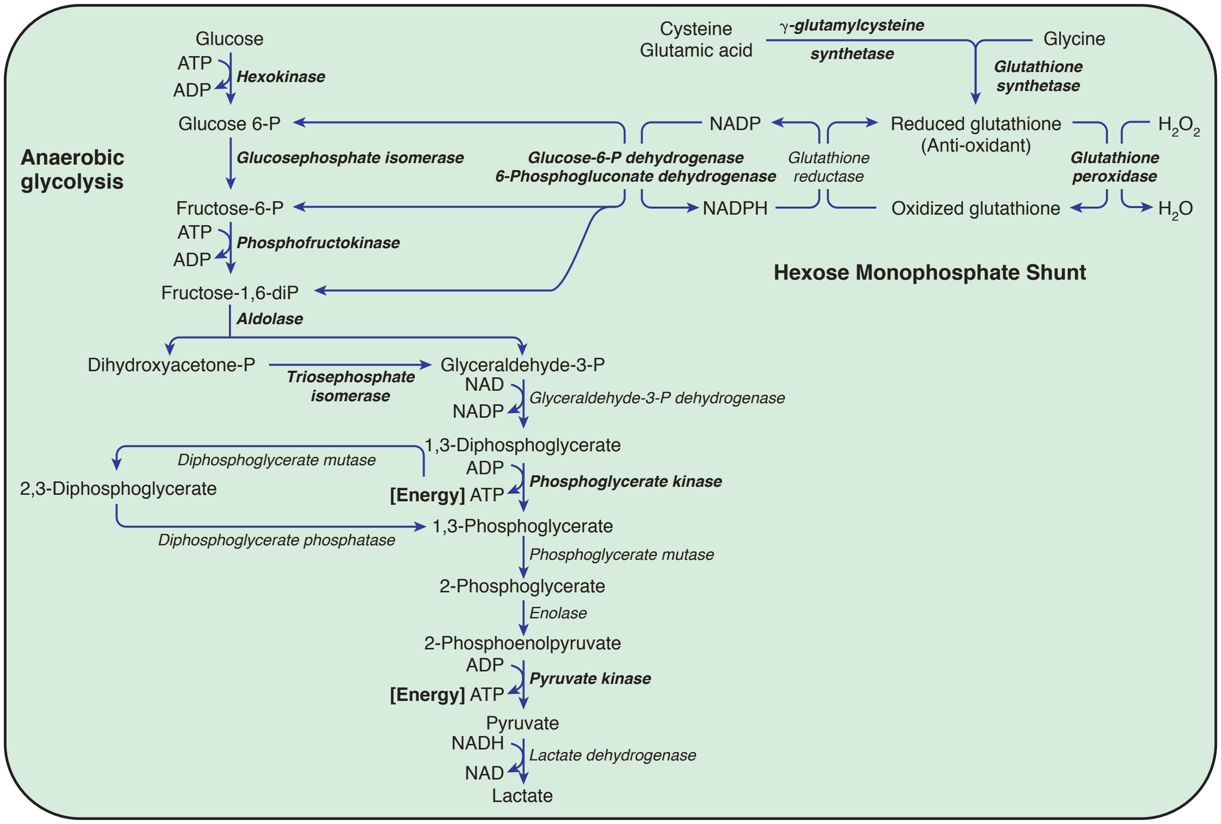

Figure 463-1 Red blood cell metabolism. Glycolysis and the hexose monophosphate pathway. The enzyme deficiencies clearly associated with hemolysis are shown in bold type. ATP, adenosine triphosphate; ADP, adenosine diphosphate; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of NADP.

of nicotinamide adenine dinucleotide (NAD^+) are found (Fig. 463-1). The concentration of 2,3-diphosphoglycerate is increased; this isomer is beneficial in facilitating oxygen release from hemoglobin but detrimental in inhibiting hexokinase and enzymes of the hexose monophosphate shunt. In addition, an unexplained decrease occurs in the sum of the adenine (ATP, adenosine diphosphate, and adenosine monophosphate) and pyridine (NAD^+ and the reduced form of NAD) nucleotides, further impairing glycolysis. As a consequence of decreased ATP, RBCs cannot maintain their potassium and water content; the cells become rigid, and their life span is considerably reduced.

ETIOLOGY

There are 2 mammalian PK genes, but only the *PKLR* gene is expressed in red cells. The human *PKLR* gene is located on chromosome 1q21. More than 180 mutations are reported in this structural gene, which codes for a 574–amino-acid protein that forms a functional tetramer. These mutations include missense, splice site, and insertion–deletion alterations, and there is some correlation of the type, location, and amino acid substitution with disease severity. Most affected patients are compound heterozygotes for 2 different PK gene defects. The many possible combinations likely account for the variability in clinical severity. The mutations 1456 C to T and 1529 G to A are the most common mutations in the white population.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

The clinical manifestations of PK deficiency vary from severe neonatal hemolytic anemia to mild, well-compensated hemolysis first noted in adulthood. Severe jaundice and anemia may occur in the neonatal period, and kernicterus has been reported. The hemolysis in older children and adults varies in severity, with hemoglobin values ranging from 8-12 g/dL associated with some pallor, jaundice, and splenomegaly. Patients with these findings usually do not require transfusion. A severe form of the disease has a relatively high incidence among the Amish of the midwestern United States. PK deficiency may possibly provide protection against falciparum malaria.

Polychromatophilia and mild macrocytosis reflect the elevated reticulocyte count. Spherocytes are uncommon, but a few spiculated pyknocytes may be found. Diagnosis relies on demonstration of a marked reduction of RBC PK activity or an increase in the Michaelis-Menten dissociation constant (K_m) for its substrate, phosphoenolpyruvate (high K_m variant). Other RBC enzyme activity is normal or elevated, reflecting the reticulocytosis. No abnormalities of hemoglobin are noted. The white cells have normal PK activity and must be rigorously excluded from the red cell hemolysates used to measure PK activity. Heterozygous carriers usually have moderately reduced levels of PK activity.

TREATMENT

Phototherapy and exchange transfusions may be indicated for hyperbilirubinemia in newborns. Transfusions of packed RBCs are necessary for severe anemia or for aplastic crises. If the anemia is consistently severe and frequent transfusions are required, iron chelation may be necessary, and splenectomy should be performed after the child is 5-6 yr of age. Although it is not curative, splenectomy may be followed by higher hemoglobin levels and by strikingly high (30-60%) reticulocyte counts. Death resulting from overwhelming pneumococcal sepsis has followed splenectomy; thus, immunization with vaccines for encapsulated organisms should be given before splenectomy, and prophylactic penicillin should be administered after the procedure.

463.2 Other Glycolytic Enzyme Deficiencies

George B. Segel

Chronic nonspherocytic hemolytic anemias of varying severity have been associated with deficiencies of other enzymes in the glycolytic pathway, including hexokinase, glucose phosphate isomerase, and aldolase, which are inherited as autosomal recessive disorders. **Phosphofructokinase deficiency,** which occurs primarily in Ashkenazi Jews in the United States, results in hemolysis associated with a myopathy classified as glycogen storage disease type VII (see Chapter 87.1). Clinically, hemolytic anemia is complicated by muscle weakness, exercise intolerance, cramps, and possibly myoglobinuria. Enzyme assays for phosphofructokinase yield low values for RBCs and muscle.

Triose phosphate isomerase deficiency is an autosomal recessive disorder affecting many systems. Affected patients have hemolytic anemia, cardiac abnormalities, and lower motor neuron and pyramidal tract impairment, with or without evidence of cerebral impairment. They usually die in early childhood. The gene for triose phosphate isomerase has been cloned and sequenced and is located on chromosome 12.

Phosphoglycerate kinase (PGK) is the first ATP-generating step in glycolysis. At least 23 kindreds with PGK deficiency have been described. PGK is the only glycolytic enzyme inherited on the X chromosome. Affected males may have progressive extrapyramidal disease, myopathy, seizures, and variable mental retardation in conjunction with hemolytic anemia. Nine Japanese patients had neural or myopathic symptoms with hemolysis; 6 had hemolysis alone; 7 had neural or myopathic symptoms alone; and 1 had no symptoms. The gene for PGK is particularly large, spanning 23 kb, and various genetic abnormalities, including nucleotide substitutions, gene deletions, missense, and splicing mutations, result in PGK deficiency.

DEFICIENCIES OF ENZYMES OF THE HEXOSE MONOPHOSPHATE PATHWAY

The most important function of the hexose monophosphate pathway is to maintain glutathione (GSH) in its reduced state as protection against the oxidation of RBCs (see Fig. 463-1). Approximately 10% of the glucose taken up by RBCs passes through this pathway to provide the reduced form of NAD phosphate (NADPH) necessary for the conversion of oxidized GSH to reduced GSH. Maintenance of reduced GSH is essential for the physiologic inactivation of oxidant compounds, such as hydrogen peroxide, that are generated within RBCs. If glutathione, or any compound or enzyme necessary for maintaining it in the reduced state, is decreased, the SH groups of the RBC membrane are oxidized and the hemoglobin becomes denatured and may precipitate into RBC inclusions called **Heinz bodies**. Once Heinz bodies have formed, an acute hemolytic process results from damage to the RBC membrane by the precipitated hemoglobin, the oxidant agent, and the action of the spleen. The damaged RBCs then are rapidly removed from the circulation.

463.3 Glucose-6-Phosphate Dehydrogenase Deficiency and Related Deficiencies

George B. Segel and Lisa R. Hackney

Glucose-6-phosphate dehydrogenase (G6PD) deficiency, the most frequent disease involving enzymes of the hexose monophosphate pathway, is responsible for 2 clinical syndromes, episodic hemolytic anemia and chronic nonspherocytic hemolytic anemia. The most common manifestations of this disorder are neonatal jaundice and episodic acute hemolytic anemia, which is induced by infections, certain drugs, and, rarely, fava beans. This X-linked deficiency affects more than 400 million people worldwide, representing an overall 4.9% global prevalence. The global distribution of this disorder parallels that of malaria, representing an example of "balanced polymorphism," in which there is an evolutionary advantage of resistance to falciparum malaria in heterozygous females that outweighs the small negative effect of affected hemizygous males.

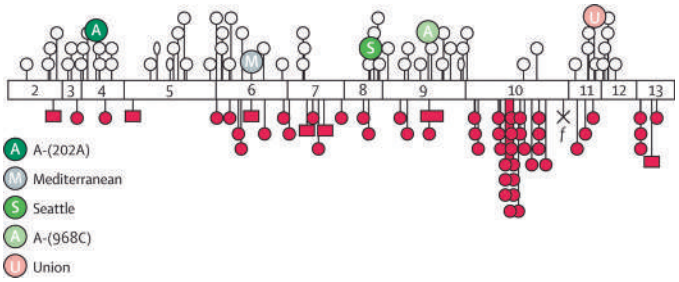

Figure 463-2 Most common mutations along coding sequence of G6PD gene. Exons are shown as *open numbered boxes. Open circles* are mutations causing classes II and III variants. *Filled circles* represent sporadic mutations giving rise to severe variants (class I). *Open ellipses* are mutations causing class IV variants. X a nonsense mutation; *f*, a splice site mutation; *filled square*, small deletion. 202A and 968C are the two sites of base substitution in G6PD-A. *(From Cappellini MD, Fiorelli G: Glucose-6-phosphate dehydrogenase deficiency,* Lancet *371:64–74, 2008.)*

The deficiency is caused by inheritance of any of a large number of abnormal alleles of the gene responsible for the synthesis of the G6PD protein. About 140 mutations have been described in the gene responsible for the synthesis of the G6PD protein. Many of these mutations are single base changes leading to amino acid substitutions and destabilization of the G6PD enzyme. A web-accessible database catalogs G6PD mutations (http://www.bioinf.org.uk/g6pd). Figure 463-2 shows some of the mutations that cause episodic versus chronic hemolysis. Milder disease is associated with mutations near the amino terminus of the G6PD molecule, and chronic nonspherocytic hemolytic anemia is associated with mutations clustered near the carboxyl terminus. The normal enzyme found in most populations is designated G6PD B+. A normal variant, designated G6PD A+, is common in Americans of African descent.

EPISODIC OR INDUCED HEMOLYTIC ANEMIA

Etiology

G6PD catalyzes the conversion of glucose 6-phosphate to 6-phosphogluconic acid. This reaction produces NADPH, which maintains GSH in the reduced, functional state (see Fig. 463-1). Reduced GSH provides protection against oxidant threats from certain drugs and infections that would otherwise cause precipitation of hemoglobin (Heinz bodies) or damage the RBC membrane.

Synthesis of RBC G6PD is determined by a gene on the X chromosome. Thus, heterozygous females have intermediate enzymatic activity and have 2 populations of RBCs: one is normal, and the other is deficient in G6PD activity. Because they have fewer susceptible cells, most heterozygous females do not have evident clinical hemolysis after exposure to oxidant drugs. Rarely, the majority of RBCs is G6PD deficient in heterozygous females because the inactivation of the normal X chromosome is random and sometimes exaggerated (Lyon-Beutler hypothesis).

Disease involving this enzyme therefore occurs more frequently in males than in females. Approximately 13% of male Americans of African descent have a mutant enzyme (**G6PD A–**) that results in a deficiency of RBC G6PD activity (5-15% of normal). Italians, Greeks, and other Mediterranean, Middle Eastern, African, and Asian ethnic groups also have a high incidence, ranging from 5% to 40%, of a variant designated **G6PD B–** (**G6PD Mediterranean**). In these variants, the G6PD activity of homozygous females or hemizygous males is <5% of normal. Therefore, the defect in Americans of African descent is less severe than that in Americans of European descent. A third mutant enzyme with markedly reduced activity (**G6PD Canton**) occurs in approximately 5% of the Chinese population.

Table 463-1 Agents Precipitating Hemolysis in Glucose-6-Phosphate Dehydrogenase Deficiency

MEDICATIONS	Others
Antibacterials	Acetanilide
Sulfonamides	Vitamin K analogs
Dapsone	Methylene blue
Trimethoprim-sulfamethoxazole	Toluidine blue
Nalidixic acid	Probenecid

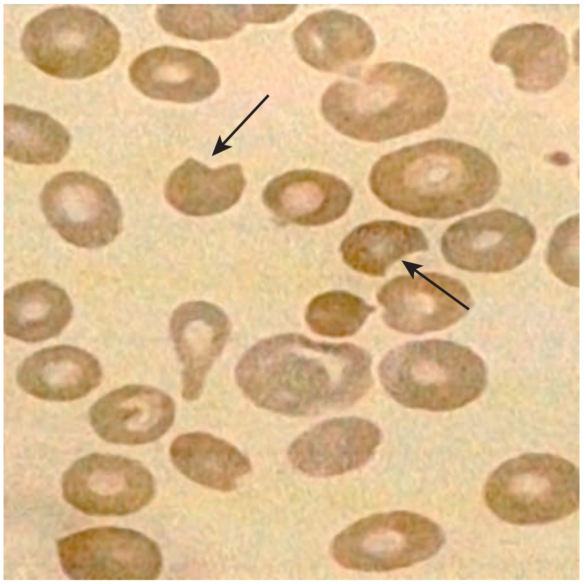

Figure 463-3 **Morphologic erythrocyte changes (anisopoikilocytosis, bite cells) during acute hemolysis in a G6PD-deficient patient.** *Arrows* show bite cells. Anisopoikilocytosis is abnormality in the shape or size of erythrocytes. *(From Cappellini MD, Fiorelli G: Glucose-6-phosphate dehydrogenase deficiency,* Lancet *371:64–74, 2008.)*

Clinical Manifestations

Most individuals with G6PD deficiency are asymptomatic, with no clinical manifestations of illness unless triggered by infection, drugs, or ingestion of fava beans. Typically, hemolysis ensues in about 24-48 hr after a patient has ingested a substance with oxidant properties. In severe cases, hemoglobinuria and jaundice result, and the hemoglobin concentration may fall precipitously. Drugs that elicit hemolysis in these individuals include aspirin, sulfonamides, rasburicase, and antimalarials, such as primaquine (Table 463-1). The degree of hemolysis varies with the inciting agent, amount ingested, and severity of the enzyme deficiency. In some individuals, ingestion of fava beans also produces an acute, severe hemolytic syndrome, known as *favism*. Fava beans contain divicine, isouramil, and convicine, which ultimately lead to production of hydrogen peroxide and other reactive oxygen products. Favism is thought to be more frequently associated with the G6PD B– variant.

In the G6PD A– variant, the stability of the folded protein dimer is impaired, and this defect is accentuated as the RBCs age. Thus, hemolysis decreases as older red cells are destroyed, even if administration of the drug is continued. This recovery results from the age-labile enzyme, which is abundant and more stable in younger RBCs. The associated reticulocytosis produces a compensated hemolytic process in which the blood hemoglobin may be only slightly decreased, despite continued exposure to the offending agent.

G6PD deficiency can produce hemolysis in the neonatal period. In G6PD A–, spontaneous hemolysis and hyperbilirubinemia have been observed in preterm infants. In newborns with the G6PD B– and G6PD Canton varieties, hyperbilirubinemia and even kernicterus may occur. Neonates with coinheritance of G6PD deficiency and a mutation of the promoter of uridine-diphosphate-glucuronyl transferase (UGT1A1), seen in Gilbert syndrome, have more severe neonatal jaundice. When a pregnant woman ingests oxidant drugs, they may be transmitted to her G6PD-deficient fetus, and hemolytic anemia and jaundice may be apparent at birth.

Laboratory Findings

The onset of acute hemolysis usually results in a precipitous fall in hemoglobin and hematocrit. If the episode is severe, the hemoglobin binding proteins, such as haptoglobin, are saturated, and free hemoglobin may appear in the plasma and subsequently in the urine. Unstained or supravital preparations of RBCs reveal precipitated hemoglobin, known as Heinz bodies. The RBC inclusions are not visible on the Wright-stained blood film. Cells that contain these inclusions are seen only within the first 3-4 days of illness because they are rapidly cleared from the blood. Also, the blood film may contain red cells with what appears to be a bite taken from their periphery and polychromasia (evidence of bluish, larger RBCs), representing reticulocytosis (Fig. 463-3).

Diagnosis

The diagnosis depends on direct or indirect demonstration of reduced G6PD activity in RBCs. By direct measurement, enzyme activity in affected persons is ≤10% of normal, and the reduction of enzyme activity is more extreme in Americans of European descent and in Asians than in Americans of African descent. Satisfactory screening tests are based on decoloration of methylene blue, reduction of methemoglobin, or fluorescence of NADPH. Immediately after a hemolytic episode, reticulocytes and young RBCs predominate. These young cells have significantly higher enzyme activity than do older cells in the A– variety (African). Testing may therefore have to be deferred for a few weeks before a diagnostically low level of enzyme can be shown. The diagnosis can be suspected when G6PD activity is within the low-normal range in the presence of a high reticulocyte count. G6PD variants also can be detected by electrophoretic and molecular analysis. G6PD deficiency should be considered in any neonatal patients with hyperbilirubinemia and borderline low G6PD activity.

Prevention and Treatment

Prevention of hemolysis constitutes the most important therapeutic measure. When possible, males belonging to ethnic groups with a significant incidence of G6PD deficiency (e.g., Greeks, southern Italians, Sephardic Jews, Filipinos, southern Chinese, Americans of African descent, and Thais) should be tested for the defect before known oxidant drugs are given. The usual doses of aspirin and trimethoprim-sulfamethoxazole do not cause clinically relevant hemolysis in the A– variety. Aspirin administered in doses used for acute rheumatic fever (60-100 mg/kg/24 hr) may produce a severe hemolytic episode. Infants with severe neonatal jaundice who belong to these ethnic groups also require testing for G6PD deficiency because of their heightened risk for this defect. If severe hemolysis has occurred,

supportive therapy may require blood transfusions, although recovery is the rule when the oxidant agent is discontinued.

CHRONIC HEMOLYTIC ANEMIAS ASSOCIATED WITH DEFICIENCY OF G6PD OR RELATED FACTORS

Chronic nonspherocytic hemolytic anemia has been associated with profound deficiency of G6PD caused by enzyme variants, particularly those defective in quantity, activity, or stability. The gene defects leading to chronic hemolysis are located primarily in the region of the NADP binding site near the carboxyl terminus of the protein (see Fig. 463-2). These include the Loma Linda, Tomah, Iowa, Beverly Hills, Nashville, Riverside, Santiago de Cuba, and Andalus variants. Persons with G6PD B–enzyme deficiency occasionally have chronic hemolysis, and the hemolytic process may worsen after ingestion of oxidant drugs. Splenectomy is of little value in these types of chronic hemolysis.

Other enzyme defects may impair the regeneration of GSH as an oxidant "sump" (see Fig. 463-1). Mild, chronic nonspherocytic anemia has been reported in association with decreased RBC GSH, resulting from γ-glutamylcysteine or GSH synthetase deficiencies. Deficiency of 6-phosphogluconate dehydrogenase has been associated primarily with drug-induced hemolysis, and hemolysis with hyperbilirubinemia has been related to a deficiency of GSH peroxidase in newborn infants.

Chapter 464

Hemolytic Anemias Resulting from Extracellular Factors—Immune Hemolytic Anemias

Charles H. Packman and George B. Segel

AUTOIMMUNE HEMOLYTIC ANEMIAS

A number of extrinsic agents and disorders may lead to premature destruction of red blood cells (RBCs). Among the most clearly defined are antibodies associated with immune hemolytic anemias. The hallmark of this group of diseases is the positive result of the direct antiglobulin (Coombs) test, which detects a coating of immunoglobulin or components of complement on the RBC surface. The most important immune hemolytic disorder in pediatric practice is hemolytic disease of the newborn (erythroblastosis fetalis), caused by transplacental transfer of maternal antibody active against the RBCs of the fetus, that is, isoimmune hemolytic anemia (see Chapter 103.2). Various other immune hemolytic anemias are autoimmune (Table 464-1) and may be idiopathic or related to various infections (Epstein-Barr virus, and rarely HIV, cytomegalovirus, and mycoplasma), immunologic diseases (systemic lupus erythematosus [SLE], rheumatoid arthritis), immunodeficiency diseases (agammaglobulinemia, autoimmune lymphoproliferative disorder, dysgammaglobulinemias), neoplasms (lymphoma, leukemia, and Hodgkin disease), or drugs (methyldopa, L-dopa). Other drugs (penicillins, cephalosporins) cause hemolysis by means of "drug-dependent antibodies"—that is antibodies directed toward the drug and in some cases toward an RBC membrane antigen as well.

AUTOIMMUNE HEMOLYTIC ANEMIAS ASSOCIATED WITH "WARM" ANTIBODIES

Etiology

In the autoimmune hemolytic anemias, autoantibodies are directed against RBC membrane antigens, but the pathogenesis of antibody induction is uncertain. The autoantibody may be produced as an inappropriate immune response to an RBC antigen or to another antigenic epitope similar to an RBC antigen, known as *molecular mimicry.* Alternatively, an infectious agent may alter the RBC membrane so that it becomes "foreign" or antigenic to the host. The antibodies usually react to epitopes (antigens) that are "public" or common to all human RBCs, such as Rh proteins.

In most instances of warm antibody hemolysis, no underlying cause can be found; this is the primary or idiopathic type (see Table 464-1). If the autoimmune hemolysis is associated with an underlying disease, such as a lymphoproliferative disorder, SLE, Evans syndrome, or immunodeficiency, it is secondary. In as many as 20% of cases of immune hemolysis, drugs may be implicated (Table 464-2).

Drugs (penicillin or sometimes cephalosporins) that cause hemolysis via the "hapten" mechanism (immune but not autoimmune) bind tightly to the RBC membrane (see Table 464-1). Antibodies to the drug, either newly or previously formed, bind to the drug molecules on RBCs, mediating their destruction in the spleen. In other cases, certain drugs, such as quinine and quinidine, do not bind to RBCs but, rather, form part of a "ternary complex," consisting of the drug, an RBC membrane antigen, and an antibody that recognizes both (see Table 464-1). Methyldopa and sometimes cephalosporins may, by unknown mechanisms, incite true autoantibodies to RBC membrane antigens, so that the presence of the drug is not required to cause hemolysis. Cephalosporins are the most common cause of drug-immune hemolytic anemia.

Clinical Manifestations

Autoimmune hemolytic anemias may occur in either of 2 general clinical patterns. The first, an acute transient type lasting 3-6 mo and occurring predominantly in children ages 2-12 yr, accounts for 70-80% of patients. It is frequently preceded by an infection, usually respiratory.

Table 464-2 Selected Drugs That Cause Immune-Mediated Hemolysis

MECHANISM	DRUG ADSORPTION (HAPTEN)	TERNARY (IMMUNE) COMPLEX	AUTOANTIBODY INDUCTION
Direct antiglobulin test	Positive (anti-IgG)	Positive (anti-C3)	Positive (anti-IgG)
Site of hemolysis	Extravascular	Intravascular	Extravascular
Medications	Penicillins Cephalosporins 6-mercaptopurine Tetracycline Oxaliplatin Hydrocortisone	Cephalosporins Quinidine Amphotericin B Hydrocortisone Rifampin (Rifadin) Metformin Quinine Probenecid Chlorpromazine Oxaliplatin	α-Methyldopa Cephalosporins Oxaliplatin L-Dopa Procainamide Ibuprofen Diclofenac (Voltaren) Interferon alfa

Ig, immunoglobulin.

Adapted from Packman CH: Hemolytic anemia resulting from immune injury. In Kaushansky K, Lichtman MA, Beutler E, et al, editors: Williams Hematology, *ed 8, New York, 2010, McGraw-Hill, pp. 777–798.*

Onset may be acute, with prostration, pallor, jaundice, fever, and hemoglobinuria, or more gradual, with primarily fatigue and pallor. The spleen is usually enlarged and is the primary site of destruction of immunoglobulin (Ig) G–coated RBCs. Underlying systemic disorders are unusual. A consistent response to glucocorticoid therapy, a low mortality rate, and full recovery are characteristic of the acute form. The other clinical pattern involves a prolonged and chronic course, which is more frequent in infants and in children >12 yr old. Hemolysis may continue for many months or years. Abnormalities involving other blood elements are common, and the response to glucocorticoids is variable and inconsistent. The mortality rate is approximately 10%, and death is often attributable to an underlying systemic disease.

Laboratory Findings

In many cases, anemia is profound, with hemoglobin levels <6 g/dL. Considerable spherocytosis and polychromasia (reflecting the reticulocyte response) are present. More than 50% of the circulating RBCs may be reticulocytes, and nucleated RBCs usually are present. In some cases, a low reticulocyte count may be found, particularly early in the episode. Leukocytosis is common. The platelet count is usually normal, but concomitant immune thrombocytopenic purpura sometimes occurs (**Evans syndrome**). The prognosis for patients with Evans syndrome is guarded, because many have or eventually have a chronic disease, including SLE, an immunodeficiency syndrome, or the autoimmune lymphoproliferative syndrome.

Results of the direct antiglobulin test are strongly positive, and free antibody can sometimes be demonstrated in the serum (indirect Coombs test). These antibodies are active at 35-40°C (95-104°F) ("warm" antibodies) and most often belong to the IgG class. They do not require complement for activity and are usually *incomplete* antibodies that do not produce agglutination in vitro. Antibodies from the serum and those eluted from the RBCs react with the RBCs of many persons in addition to those of the patient. They often have been regarded as nonspecific panagglutinins, but careful studies have revealed specificity for RBC antigens of the Rh system in 70% of patients (≈50% of adult patients). Complement, particularly fragments of C3b, may be detected on the RBCs in conjunction with IgG. The Coombs test result is *rarely* negative *because of* the limited sensitivity of the Coombs reaction. A minimum of 260-400 molecules of IgG per cell is necessary on the RBC membrane to produce a positive reaction. Special tests are required to detect the antibody in cases of "Coombs-negative" autoimmune hemolytic anemia. In warm antibody hemolytic anemia, the direct Coombs test may detect IgG alone, both IgG– and complement fragments, or solely complement fragments if the level of RBC-bound IgG is below the detection limit of the anti-IgG Coombs reagent.

Treatment

Transfusions may provide only transient benefit but may be lifesaving in cases of severe anemia by providing delivery of oxygen until the effect of other treatment is observed. All tested units for transfusion are serologically incompatible. It is important to identify the patient's ABO blood group to avoid a hemolytic transfusion reaction mediated by anti-A or anti-B. The blood bank should also test for the presence of an underlying alloantibody, which could cause rapid hemolysis of transfused red cells. Patients who have neither been previously transfused nor pregnant are unlikely to harbor an alloantibody. Early consultation between the clinician and the blood bank physician is essential. Failure to transfuse a profoundly anemic infant or child may lead to serious morbidity and even death.

Patients with mild disease and compensated hemolysis may not require any treatment. If the hemolysis is severe and results in significant anemia or symptoms, treatment with glucocorticoids is initiated. Glucocorticoids decrease the rate of hemolysis by blocking macrophage function by downregulating Fcγ receptor expression, decreasing the production of the autoantibody, and perhaps enhancing the elution of antibody from the RBCs. Prednisone or its equivalent is administered at a dose of 2 mg/kg/24 hr. In some patients with severe hemolysis, doses of prednisone of up to 6 mg/kg/24 hr may be required to reduce the rate of hemolysis. Treatment should be continued until the rate of hemolysis decreases, and then the dose gradually reduced. If relapse occurs, resumption of the full dosage may be necessary. The disease tends to remit spontaneously within a few weeks or months. The Coombs test result may remain positive even after the hemoglobin level returns to normal. It is usually safe to discontinue prednisone once the direct Coombs test result becomes negative. When hemolytic anemia remains severe despite glucocorticoid therapy, or if very large doses are necessary to maintain a reasonable hemoglobin level, IV immunoglobulin may be tried. Rituximab, a monoclonal antibody that targets B lymphocytes, the source of antibody production, is useful in chronic cases refractory to conventional therapy. Plasmapheresis has been used in refractory cases but generally is not helpful. Splenectomy may be beneficial but is complicated by a heightened risk of infection with encapsulated organisms, particularly in patients <6 yr. Prophylaxis with appropriate vaccines (pneumococcal, meningococcal, and *Haemophilus influenzae* type b) before splenectomy and with oral penicillin after splenectomy are indicated.

Course and Prognosis

Acute idiopathic autoimmune hemolytic disease in childhood varies in severity but is self-limited; death from untreatable anemia is rare. Approximately 30% of patients have chronic hemolysis, often associated with an underlying disease, such as SLE, lymphoma, or leukemia.

The presence of antiphospholipid antibodies in adult patients with immune hemolysis predisposes to thrombosis. Mortality in chronic cases depends on the primary disorder.

AUTOIMMUNE HEMOLYTIC ANEMIAS ASSOCIATED WITH "COLD" ANTIBODIES

"Cold" antibodies agglutinate RBCs at temperatures <37°C (98.6°F). They are primarily of the IgM class and require complement for hemolytic activity. The highest temperature at which RBC agglutination occurs is called the *thermal amplitude.* A higher thermal amplitude antibody—that is, one that can bind to RBCs at temperatures achievable in the body—results in hemolysis with exposure to a cold environment. High antibody titers are associated with a high thermal amplitude.

Cold Agglutinin Disease

Cold antibodies usually have specificity for the oligosaccharide antigens of the I/i system. They may occur in primary or idiopathic cold agglutinin disease, secondary to infections such as those from *Mycoplasma pneumoniae* and Epstein-Barr virus, or secondary to lymphoproliferative disorders. After *M. pneumoniae* infection, the anti-I levels may increase considerably, and occasionally, enormous increases may occur to titers ≥1/30,000. The antibody has specificity for the I antigen and thus reacts poorly with human cord RBCs, which possess the i antigen but exhibit low levels of I. Patients with infectious mononucleosis occasionally have cold agglutinin disease, and the antibodies in these patients often have anti-i specificity. This antibody causes less hemolysis in adults than in children because adults have fewer i molecules on their RBCs. Spontaneous RBC agglutination is observed in the cold and in vitro, and RBC aggregates are seen on the blood film. Mean corpuscular volume may be spuriously elevated because of RBC agglutination. The severity of the hemolysis is related to the thermal amplitude of the antibody, which itself partly depends on the IgM antibody titer.

When very high titers of cold antibodies are present and active near body temperature, severe intravascular hemolysis with hemoglobinemia and hemoglobinuria may occur and may be heightened on a patient's exposure to cold (external temperature or ingested foods). Each IgM molecule has the potential to activate a C1 molecule so that large amounts of complement are found on the RBCs in cold agglutinin disease. These sensitized RBCs may undergo intravascular complement-mediated lysis or may be destroyed in the liver and spleen. Only complement, not IgM, is detected on RBCs because the IgM is removed during the washing steps of the direct antiglobulin test.

Cold agglutinin disease is less common in children than in adults and more frequently results in an acute, self-limited episode of hemolysis. Glucocorticoids are much less effective in cold agglutinin disease than in disease with warm antibodies. Patients should avoid exposure to cold and should be treated for underlying disease. In the uncommon patients with severe hemolytic disease, treatment includes immunosuppression and plasmapheresis. Successful treatment of cold agglutinin disease has been reported with the monoclonal antibody rituximab, which effectively depletes B lymphocytes. Splenectomy is not useful in cold agglutinin disease.

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria is mediated by the Donath-Landsteiner (D-L) hemolysin, which is an IgG cold-reactive autoantibody with anti-P specificity. In vitro, the D-L antibody binds to RBCs in the cold and the RBCs are lysed by complement as the temperature is increased to 37 degrees C. A similar sequence is thought to occur in vivo as RBCs move from the cooler extremities to warmer parts of the circulation. Most reported cases are self-limited; many patients experience only one paroxysm of hemolysis. Congenital or acquired syphilis used to be the most common underlying cause of paroxysmal cold hemoglobinuria, but today, most cases are associated with nonspecific viral infections. This disorder accounts for 30% of immune hemolytic episodes among children. Treatment includes transfusion for severe anemia and avoidance of cold ambient temperatures.

Chapter 465

Hemolytic Anemias Secondary to Other Extracellular Factors

George B. Segel

FRAGMENTATION HEMOLYSIS

(See Table 457-1 in Chapter 457.)

Red blood cell (RBC) destruction may occur in hemolytic anemias because of mechanical injury as the cells traverse a damaged vascular bed. Damage may be microvascular when RBCs are sheared by fibrin in the capillaries during intravascular coagulation or when renovascular disease accompanies the hemolytic-uremic syndrome (HUS) (see Chapter 518) or thrombotic thrombocytopenic purpura (see Chapter 484.5). Larger vessels may be involved in Kasabach-Merritt syndrome (giant hemangioma and thrombocytopenia; see Chapter 505) or when a replacement heart valve is poorly epithelialized. The blood film shows many "schistocytes," or fragmented cells, as well as polychromatophilia, reflecting the reticulocytosis (see Fig. 458-4*F* in Chapter 458). Secondary iron deficiency may complicate the intravascular hemolysis because of urinary hemoglobin and hemosiderin iron loss (see Fig. 457-2 in Chapter 457). Treatment should be directed toward the underlying condition, and the prognosis depends on the effectiveness of this treatment. The benefit of transfusion may be transient because the transfused cells are destroyed as quickly as those produced by the patient.

It is critical to determine the precise etiology of the fragmentation hemolysis because the treatment depends on the underlying problem (Table 465-1). Thrombotic thrombocytopenic purpura results from an antibody to an enzyme (AdamTS13) that regulates the size of von Willebrand multimers. The lack of this enzyme results in a marked increase in multimer size and a resultant thrombotic microangiopathy. The treatment involves plasmapheresis (PLEX) to remove the antibody and replace the AdamTS13. In contrast, HUS results from *Shiga* toxin produced by *Escherichia coli* 0157 and may not be helped by PLEX. Atypical HUS involves activation of the alternative complement pathway and is currently treated with eculizumab (anti C5), an inhibitor of the complement pathway. PLEX may reduce the RBC fragmentation and improve the platelet count but has little effect on the tissue (kidney) vasculopathy and thus is not usually recommended. Pneumococcal-induced HUS results from neuraminidase produced by the bacteria, which damages the membranes of the RBCs and the kidney, exposing the T-antigen. Plasma contains natural antibody to the T-antigen producing hemolysis, renal damage, and a thrombotic microangiopathy.

THERMAL INJURY

Extensive burns may directly damage the RBCs and cause hemolysis that results in the formation of spherocytes. Blood loss and marrow suppression may contribute to anemia and require blood transfusion. Erythropoietin (EPO) has been used as treatment for diminished RBC production.

RENAL DISEASE

The anemia of uremia is multifactorial in origin. EPO production may be decreased and the marrow suppressed by toxic metabolites. Furthermore, the RBC life span often is shortened owing to retention of

Table 465-1 Thrombotic Microangiopathies

DISEASE*	PATHOPHYSIOLOGY	LAB FINDINGS	MANAGEMENT
TTP	Ab to AdamTS13	AdamTS13 <10%[†] Ab to AdamTS13	PLEX with plasma
HUS	*E. coli* 0157, *Shiga* toxin	*E. coli* 0157, *Shiga* toxin	Supportive ? value of PLEX
aHUS	Complement-mediated alternative pathway	AdamTS13 >10% Decreased factors H and I (inhibitors of complement)[‡]	Eculizumab (ab to C5) PLEX not indicated
Pneumococcal-induced HUS	Neuraminidase-induced RBC, platelet, and kidney damage Exposure of T-antigen on RBC and kidney	Pneumococcal infection AdamTS13 >10%	PLEX with albumin for neuraminidase and endogenous T ab removal
DIC	Sepsis, shock, endotoxin	Decreased fibrinogen, increased fibrin split products, decreased clotting factors and platelets	Treat underlying condition; replace factors and platelets if bleeding

*All show fragmentation hemolytic anemia, thrombocytopenia and potential renal and other organ damage. An elevated lactate dehydrogenase and reduced haptoglobin usually are present secondary to hemolysis.
†Rarely a congenital defect in AdamTS13.
‡May be related to inherited defect in factor H or I.
Ab/ab, antibody; aHUS, atypical hemolytic uremic syndrome; DIC, disseminated intravascular coagulation; *E. coli*, *Escherichia coli*; HUS, hemolytic uremic syndrome; PLEX, plasmapheresis; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura.

metabolites and organic acidemia. The use of EPO in chronic renal disease has markedly decreased the need for blood transfusion.

LIVER DISEASE

A change in the ratio of cholesterol to phospholipids in the plasma may result in changes in the composition of the RBC membrane and shortening of the RBC life span. Some patients with liver disease have many target RBCs on the blood film, whereas others have a preponderance of spiculated cells. These morphologic changes reflect the alterations in the plasma lipid composition.

TOXINS AND VENOMS

Bacterial sepsis caused by *Haemophilus influenzae*, staphylococci, or streptococci may be complicated by accompanying hemolysis. Particularly severe hemolytic anemia has been observed in clostridial infections and results from a hemolytic clostridial toxin. Large numbers of spherocytes may be seen on the blood film. Spherocytic hemolysis also may be noted after bites by various snakes, including cobras, vipers, and rattlesnakes, which have phospholipases in their venom. Large numbers of bites by insects, such as bees, wasps, and yellow jackets, also may cause spherocytic hemolysis by a similar mechanism (see Chapter 725).

WILSON DISEASE

(See Chapter 357.2.)

An acute and self-limited episode of hemolytic anemia may precede by years the onset of hepatic or neurologic symptoms in Wilson disease. This event appears to result from the toxic effects of free copper on the RBC membrane. The blood film often (but not always) shows large numbers of spherocytes, and the Coombs test result is negative. Because early diagnosis of Wilson disease permits prophylactic treatment with penicillamine and prevention of hepatic and neurologic disease, correct assessment of this rare type of hemolysis is important.

Section 4

Polycythemia (Erythrocytosis)

Chapter 466

Polycythemia

Amanda M. Brandow and Bruce M. Camitta

Polycythemia exists when the red blood cell (RBC) count, hemoglobin level, and total RBC volume all exceed the upper limits of normal. In postpubertal individuals, an RBC mass >25% above the mean normal value (based on body surface area) or a hemoglobin >18.5 g/dL (in males) or >16.5 g/dL (in females) indicate absolute erythrocytosis. A decrease in plasma volume, such as occurs in acute dehydration and burns, may result in a high hemoglobin value. These situations are more accurately designated as *hemoconcentration* or *relative polycythemia* because the RBC mass is not increased and normalization of the plasma volume restores hemoglobin to normal levels. Once the diagnosis of true polycythemia is made, sequential studies should be done to determine the underlying etiology (Fig. 466-1).

CLONAL (PRIMARY) POLYCYTHEMIA (POLYCYTHEMIA RUBRA VERA)

Pathogenesis

Polycythemia vera is an acquired clonal myeloproliferative disorder. Although primarily manifesting as erythrocytosis, thrombocytosis and leukocytosis can also be seen. When isolated severe thrombocytosis exists in the absence of erythrocytosis, the myeloproliferative disorder is called *essential thrombocythemia*. Polycythemia vera is rare in children. A gain-of-function mutation of *JAK2,* a cytoplasmic tyrosine kinase, is found in more than 90% of adult patients with polycythemia vera, but in <30% of children with this condition. The erythropoietin

Table 466-1	WHO Diagnostic Criteria for Polycythemia Vera
MAJOR CRITERIA 1. Hb >18.5 g/dL (men) or Hb >16.5 g/dL (women) *or* Hb or Hct >99th percentile of reference range for age, sex, or altitude of residence *or* Hb >17 g/dL (men) or Hb >15 g/dL (women) if associated with a sustained increase of ≥2 g/dL from baseline that cannot be attributed to correction of iron deficiency *or* elevated red cell mass >25% above mean normal predicted value 2. Presence of *JAK2* or similar mutation	
MINOR CRITERIA 1. Bone marrow trilineage myeloproliferation 2. Subnormal serum erythropoietin level 3. Endogenous erythroid colony growth	
DIAGNOSIS Both major criteria and one minor criteria *or* first major criteria and 2 minor criteria.	

Hb, hemoglobin; Hct, hematocrit.
From Tefferi A, Vardiman JW: Classification and diagnosis of myeloproliferative neoplasms: the 2008 World Health Organization criteria and point-of-care diagnostic algorithms. Leukemia *22:14–22, 2008.*

receptor is normal, and serum erythropoietin levels are normal or low. In vitro cultures do not require added erythropoietin to stimulate growth of erythroid precursors. Risk factors for development of polycythemia vera include a family history of polycythemia vera and presence of an autoimmune disorder such as Crohn disease.

Clinical Manifestations

Patients with polycythemia vera usually have hepatosplenomegaly. Erythrocytosis may cause hypertension, headache, shortness of breath, or neurologic symptoms and increases the risk of thrombosis. Granulocytosis may cause diarrhea or pruritus from histamine release. Thrombocytosis (with or without platelet dysfunction) may cause thrombosis or hemorrhage. Table 466-1 lists the diagnostic criteria for polycythemia vera.

Treatment

Phlebotomy is the initial treatment of choice to alleviate symptoms of hyperviscosity and decrease the risk of thrombosis. Iron supplementation should be given to prevent viscosity problems from iron-deficient microcytosis or thrombocytosis. In patients with marked thrombocytosis, antiplatelet agents (e.g., aspirin) may reduce the risks of thrombosis and bleeding. If these treatments are unsuccessful or the patient has progressive hepatosplenomegaly, antiproliferative treatments (hydroxyurea, anagrelide, interferon-α) may be helpful. The use of JAK2 inhibitors is an active area of investigation. Transformation of the disease into myelofibrosis or acute leukemia is rare in children. Prolonged survival is not unusual.

Chapter 467

Non-Clonal Polycythemia

Amanda M. Brandow and
Bruce M. Camitta

PATHOGENESIS

Nonclonal polycythemia is diagnosed when polycythemia is caused by a physiologic process that is not derived from a single cell (Table 467-1). Nonclonal polycythemia can be congenital or acquired (secondary).

Congenital Polycythemia

Lifelong or familial polycythemia should trigger a search for a congenital problem. These inherited conditions may be transmitted as dominant or recessive disorders. Autosomal dominant causes include hemoglobins that have increased oxygen affinity (P_{50} [partial pressure of oxygen in the blood at which the hemoglobin is 50% saturated] <20 mm Hg), erythropoietin receptor mutations resulting in an enhanced effect of erythropoietin or mutations in the von Hippel–Lindau gene that result in altered intracellular oxygen sensing. Another rare cause is autosomal recessive 2,3-ddiphosphoglyceric acid deficiency, which leads to a left shift of the oxygen dissociation curve, increased oxygen affinity, and consequent polycythemia.

Table 467-1	Differential Diagnosis of Polycythemia

CLONAL (PRIMARY)
Polycythemia vera

NONCLONAL
Congenital
High-oxygen affinity hemoglobinopathy (e.g., hemoglobin Chesapeake, Malmo, San Diego)
Erythropoietin receptor mutations (primary familial and congenital polycythemia [PFCP])
Methemoglobin reductase deficiency
Hemoglobin M disease
2,3-Diphosphoglycerate deficiency
Acquired
Hormonal
- Adrenal disease
  - Virilizing hyperplasia, Cushing syndrome
- Anabolic steroid therapy
- Malignant tumors
  - Adrenal, cerebellar, hepatic, other
- Renal disease
  - Cysts, hydronephrosis, renal artery stenosis

Hypoxia
- Altitude
- Cardiac disease
- Lung disease
- Central hypoventilation
- Chronic carbon monoxide exposure

Neonatal
Delayed cord clamping (placental-fetal transfusion)
- Normal intrauterine environment
- Placental insufficiency (preeclampsia, maternal chronic hypertension, placental abruption)
- Twin–twin or maternal–fetal hemorrhage
- Perinatal asphyxia
- Infants of diabetic mothers
- Intrauterine growth retardation
- Trisomy 13, 18, or 21
- Adrenal hyperplasia
- Thyrotoxicosis

Spurious
Plasma volume decrease

Subtle decreases in oxygen delivery to tissues may cause polycythemia. Congenital methemoglobinemia resulting from an autosomal recessive deficiency of cytochrome b5 reductase may cause cyanosis and polycythemia (see Chapter 462.7). Most affected individuals are asymptomatic. Neurologic abnormalities may be present in patients whose enzyme deficits are not limited to hematopoietic cells. Hemoglobin M disease (autosomal dominant) causes methemoglobinemia and can lead to polycythemia. Cyanosis may occur in the presence of as little as 1.5 g/dL of methemoglobin but is uncommon in other hemoglobin variants unless hyperviscosity results in localized hypoxemia.

Acquired Polycythemia

Polycythemia may be present in clinical situations associated with chronic arterial oxygen desaturation. Cardiovascular defects involving right-to-left shunts and pulmonary diseases interfering with proper oxygenation are the most common causes of hypoxic polycythemia. Clinical findings usually include cyanosis, hyperemia of the sclerae and mucous membranes, and clubbing of the fingers. As the hematocrit rises to >65%, clinical manifestations of hyperviscosity, such as headache and hypertension, may require phlebotomy. Living at high altitudes also causes hypoxic polycythemia; the hemoglobin level increases approximately 4% for each rise of 1,000 m in altitude. Partial obstruction of a renal artery rarely results in polycythemia. Polycythemia has also been associated with benign and malignant tumors that secrete erythropoietin. Exogenous or endogenous excess of anabolic steroids also may cause polycythemia. A common spurious cause is a decrease in plasma volume such as in moderate to severe dehydration.

DIAGNOSIS

Figure 466-1 outlines sequential studies to evaluate polycythemia.

TREATMENT

For mild disease, observation is sufficient. When the hematocrit is >65-70% (hemoglobin >23 g/dL), blood viscosity markedly increases. Periodic phlebotomy may prevent or decrease symptoms such as headache, dizziness, or exertional dyspnea. Apheresed blood should be replaced with plasma or saline to prevent hypovolemia in patients accustomed to a chronically elevated total blood volume. Increased demand for red blood cell production may cause iron deficiency. Iron-deficient microcytic red cells are more rigid, further increasing the risk of intracranial and other thromboses in patients with polycythemia. Periodic assessment of iron status, with treatment of iron deficiency, should be performed.

Section 5

The Pancytopenias

Chapter 468

The Inherited Pancytopenias

Yigal Dror and Melvin H. Freedman

Pancytopenia refers to a reduction below normal values of all 3 peripheral blood lineages: leukocytes, platelets, and erythrocytes. Pancytopenia requires microscopic examination of a bone marrow biopsy specimen and a marrow aspirate to assess overall cellularity and morphology. There are 3 general categories of pancytopenia depending on the marrow findings.

Hypocellular marrow on biopsy is seen with inherited ("constitutional") marrow failure syndromes, acquired aplastic anemia of varied etiologies (see Chapter 469), the hypoplastic variant of myelodysplastic syndrome (MDS), and some cases of paroxysmal nocturnal hemoglobinuria with pancytopenia.

Cellular marrow is seen (a) with primary bone marrow disease, such as acute leukemia (see Chapter 494), and MDS, and (b) secondary to systemic disease, such as autoimmune disorders (systemic lupus erythematosus; Chapter 158), vitamin B_{12} or folate deficiency (see Chapters 49.6 and 49.7), storage disease (Gaucher and Niemann-Pick diseases; see Chapter 86.4), overwhelming infection, sarcoidosis, and hypersplenism.

Bone marrow infiltration can cause pancytopenia in metastatic solid tumors, myelofibrosis, hemophagocytic lymphohistiocytosis (see Chapter 507) and osteopetrosis (see Chapter 699).

Inherited ("constitutional") pancytopenia is defined as a decrease in marrow production of the 3 major hematopoietic lineages that occurs on an inherited basis, resulting in anemia, neutropenia, and thrombocytopenia. Any of these conditions (Tables 468-1 and 468-2) can be transmitted as a simple mendelian disorder by mutant genes with inherited patterns of autosomal dominant, autosomal recessive, or X-linked types. Modifying genes and acquired factors may also be operative. Inherited pancytopenias account for approximately 30% of cases of pediatric marrow failure. Fanconi anemia is the most common of these disorders.

FANCONI ANEMIA

Etiology and Epidemiology

Fanconi anemia (FA) is primarily inherited in an autosomal recessive manner (one uncommon form is X-linked recessive). It occurs in all racial and ethnic groups. At presentation, patients with FA may have: (1) typical physical anomalies and abnormal hematologic findings (majority of the patients); (2) normal physical features but abnormal hematologic findings (about one-third of patients); or (3) physical anomalies and normal hematologic findings (unknown percentage). There can be sibling discordance in clinical and hematologic findings, even in affected monozygotic twins. Approximately 75% of patients are 3-14 yr of age at the time of diagnosis.

Table 468-1 Inherited Pancytopenia Syndromes

Reticular dysgenesis
Unclassified inherited bone marrow failure syndromes
Other genetic syndromes
Down syndrome
Dubowitz syndrome
Seckel syndrome
Schimke immunoosseous dysplasia
Cartilage-hair hypoplasia
Noonan syndrome

Pathology

Patients have abnormal chromosome fragility, which is seen in metaphase preparations of peripheral blood lymphocytes cultured with phytohemagglutinin and enhanced by adding clastogenic agents such as diepoxybutane (DEB) and mitomycin C. Cell fusion of FA cells with normal cells or with cells from some unrelated patients with FA produces a corrective effect on chromosomal fragility, a process called *complementation.* This phenomenon allows subtyping of cases of FA into discrete complementation groups. Fifteen different complementation groups have been identified with different FA (*FANC*) genes that are mutated in each of them: A, B, C, D1/BRCA2, D2, E, F, G, I, J, L, M, N, O, P). An additional 2 genes, *XRCC2* and *ECCR4,* have been published and need further studies. After their discovery, the genes are prefixed with *FANC* (*FANCA*, *FANCB,* and so on). *FANCD1* is identical to the breast cancer susceptibility gene, *BRCA2.* The protein products of wild-type *FANC* genes are involved in the DNA damage recognition and repair biochemical pathways. Therefore, mutant gene proteins lead to genomic instability and chromosome fragility. An inability of FA cells to remove oxygen-free radicals, resulting in oxidative damage, is an additional mechanism that may contribute to the disease pathogenesis. Leukocyte telomere length is significantly shortened but telomerase activity is increased, suggesting a high proliferative rate of marrow progenitors that ultimately leads to their premature senescence. Increased marrow cell apoptosis occurs and is

Table 468-2 Distinguishing Clinical Features of the Inherited Bone Marrow Failure Syndromes That May Be Initially Diagnosed in Adulthood

Distinguishing Features	DISEASES		
	Fanconi Anemia	**Dyskeratosis Congenita**	**Schwachman-Diamond Anemia**
History	Skeletal and renal malformations, low birthweight, pancytopenia, family member with bone marrow failure, MDS, acute myelogenous leukemia (AML), or squamous cell carcinoma at an early age; family member with Fanconi anemia	Intrauterine growth retardation, developmental delay, and short stature. Family history of MDS, AML, marrow failure, abnormal fingernails or toenails, leukoplakia, head and neck cancer, or pulmonary fibrosis	Pancreatic insufficiency, low birth weight, metaphyseal dysostosis, initial neutropenia, delayed development
Physical findings	Thumb and radial malformations, hyperpigmented skin lesions (café-au-lait spots), short stature, MDS, AML, squamous cell carcinoma at young age, renal and cardiac malformations, microcephaly, hypogonadism	Lacy reticular pigmentation of skin, dystrophic fingernails and toenails, premature graying of hair, hair loss, short stature, oral leukoplakia, squamous cell cancer of head and neck, pulmonary fibrosis, osteopenia, hypogonadism	Short stature, abnormal thorax
Genes inactivated	*FANCA, FANCB, FANCC, FANCD1* (aka *BRCA2*), *FANCD2, FANCE, FANCF, FANCG* (aka *XRCC9*), *FANCI, FANCJ* (aka *BACH1* and *BRIP1*), *FANCL* (aka *PHF9* and *POG*), *FANCM* (aka *Hef*), and *FANCN* (aka *PALB2*) These genes encode proteins known to protect the genome from excessive damage induced by chemical crosslinking agents. These genes account for most cases of Fanconi anemia	*DKC1, TERC, TERT, TINF2, NOLA2,* and *NOLA3* These genes encode proteins known to participate in maintenance of telomeres. They account for only half of dyskeratosis cases, so there are additional genes to be discovered	*SBDS* autosomal recessive marrow clonal expansion in ~15%
Screening and diagnostic tests	1. Chromosomal breakage test (in response to mitomycin C or diepoxybutane) 2. Complementation analysis (flow cytometric analysis of G_2 arrest in melphalan-exposed cells after transduction with retroviral vectors expressing normal Fanconi anemia genes) 3. Gene sequencing	1. Quantitative analysis of telomere length ("flow FISH") 2. Gene sequencing	CT demonstrates fatty infiltration of pancreas Gene testing May evolve to myelodysplasia or leukemia Absence of pancreatic lipomatosis, fecal fat, or dysostosis does not rule out diagnosis

ADA, adenosine deaminase; FISH, fluorescent in situ hybridization.

Modified from Bagby GC: Aplastic anemia and related bone marrow failure states. In Goldman L, Schafer AI, editors, Goldman's Cecil medicine, *ed 24, Philadelphia, 2012, WB Saunders, Table 168-3, p. 1086.*

mediated by Fas, a membrane glycoprotein receptor containing an integral death domain. A consistent finding is diminished cellular interleukin-6 production along with markedly heightened tumor necrosis factor-α generation.

Clinical Manifestations

The most common anomaly in FA is hyperpigmentation of the trunk, neck, and intertriginous areas, as well as café-au-lait spots and vitiligo, alone or in combination (Fig. 468-1 and Table 468-3). Half the patients have short stature. In some patients, growth failure is aggravated by abnormal growth hormone secretion or with hypothyroidism. Absence of radii and thumbs that are hypoplastic, supernumerary, bifid, or absent are common. The "r" radial pulse may be weak or absent. Anomalies of the feet, congenital hip dislocation, and leg abnormalities are seen. A male patient with FA may have an underdeveloped penis; undescended, atrophic, or absence of the testes; and hypospadias or phimosis. Females can have malformations of the vagina, uterus, and ovary. Many patients have a FA "facies," including microcephaly, small eyes, epicanthal folds, and abnormal shape, size, or positioning of the ears (Fig. 468-1). Ectopic, pelvic, or horseshoe kidneys are detected by imaging and may show other organs as duplicated, hypoplastic, dysplastic, or absent kidneys. Cardiovascular and gastrointestinal malformations also occur. Approximately 10% of patients with FA are cognitively delayed.

Table 468-3 Characteristic Physical Anomalies in Fanconi Anemia

ANOMALY	APPROXIMATE FREQUENCY (% OF PATIENTS)
Skin pigment changes ± café-au-lait spots	55
Short stature	51
Upper limb abnormalities (thumbs, hands, radii, ulnas)	43
Hypogonadal and genital changes (mostly male)	35
Other skeletal findings (head/face, neck, spine)	30
Eye/lid/epicanthal fold anomalies	23
Renal malformations	21
Gastrointestinal/cardiopulmonary malformations	11
Hip, leg, foot, toe abnormalities	10
Ear anomalies (external and internal), deafness	9

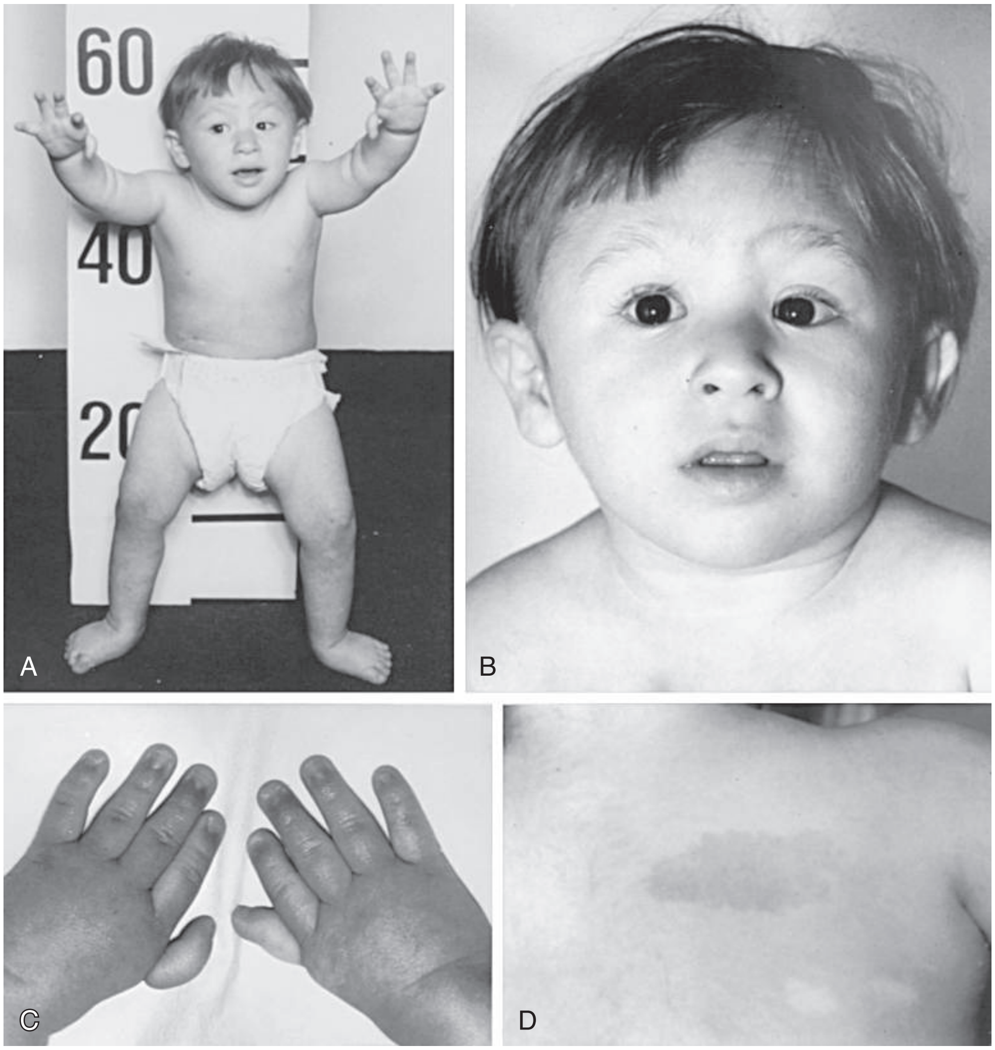

Figure 468-1 A 3 yr old boy with Fanconi anemia who exhibits several classic phenotype features. **A,** Front view. **B,** Face. **C,** Hands. **D,** Back right shoulder. The features to be noted include short stature, dislocated hips, microcephaly, a broad nasal base, epicanthal folds, micrognathia, thumbs attached by a thread, and café-au-lait spots with hypopigmented areas beneath. *(From Nathan DC, Orkin SH, Ginsburg D, et al, editors:* Nathan and Oski's hematology of infancy and childhood, *ed 6, vol I, Philadelphia, 2003, WB Saunders, p. 285.)*

Laboratory Findings

Marrow failure usually ensues in the 1st decade of life. Thrombocytopenia and red blood cell macrocytosis often appears initially, with subsequent onset of granulocytopenia and then anemia. Severe aplasia develops in most cases, but its full expression is variable and evolves over a period of months to years. The marrow becomes progressively hypocellular and fatty, like that in severe acquired aplastic anemia. Chromosome fragility is indicated by spontaneously occurring chromatid breaks, rearrangements, gaps, endoreduplications, and chromatid exchanges in blood lymphocytes cultured with phytohemagglutinin as well as in cultured skin fibroblasts, underscoring the constitutional nature of the disorder. With addition of DEB or mitomycin C, fragility is strikingly enhanced in lymphocyte cultures of patients with FA in comparison with those of controls. For prenatal diagnosis, abnormal chromosome breakage analysis and genetic testing can be performed in amniotic fluid cells or in tissue from a chorionic villus biopsy.

Complications

In addition to the low blood counts and physical anomalies, a major feature of the phenotype of FA is the propensity for cancer. The most frequent solid tumors are squamous cell carcinomas of the head, neck, and upper esophagus, followed by carcinomas of the vulva and/or anus, cervix, and lower esophagus. Human papilloma virus is suspected in the pathogenesis. Some patients experience oral cancer after bone marrow transplantation; it is unclear whether this treatment has an effect on the incidence. Benign and malignant liver tumors occur (adenomas, hepatomas) are usually associated with androgen therapy for aplastic anemia. Androgens are also implicated in the etiology of peliosis hepatis (blood-filled hepatic sinusoids). Peliosis hepatis is reversible when androgen therapy is discontinued, and tumors may regress. Clonal marrow cytogenetic abnormalities are common in FA, and at follow-up can either be stable, intermittently detected, or progressive and develop to advanced MDS and acute myelogenous leukemia. Approximately 15% of patients with FA are at risk for acute leukemia by the age of 35 yr.

Diagnosis

FA should be considered in all children and young adults with unexplained cytopenias. Abnormal hematologic findings and characteristic physical anomalies suggest the diagnosis, which is confirmed with a lymphocyte chromosomal breakage study using DEB. No other inherited pancytopenia is associated with a prominent in vitro hypersensitivity to DEB or mitomycin C by the chromosomal breakage study. Ten percent to 15% of patients with suspected FA have "somatic mosaicism" and their lymphocytes may not show characteristic high level of chromosomal fragility because of mixed populations of somatic cells, some with 2 abnormal alleles and some with 1 (caused by spontaneous somatic gene correction in a portion of the cells). Testing of skin fibroblasts instead of lymphocytes confirms the diagnosis.

Most patients have stable elevations of serum α-fetoprotein expressed constitutively, independent of liver complications or androgen therapy. Because of its low specificity compared to the chromosomal fragility and molecular tests the laboratory measurement of serum α-fetoprotein has not been widely used as a screening test.

As a result of the large number of *FANC* genes, genetic diagnosis has traditionally been commenced with complementation testing. This is done by determining whether cellular hypersensitivity to crosslinking agents (e.g., mitomycin C or radiation) or immunoblotting for *FANCD2* is restored after generating hybridoma of the patient cells with known genetic complementation cells or after transducing the cells with a known *FANC* gene. The mutant gene or the complementation group is deduced when a specific wild-type *FANC* gene corrects the abnormal chromosome fragility.

Treatment

A hematologist and a multidisciplinary team should supervise patients with FA. If the hematologic findings are stable and there are no transfusion requirements, observation is indicated. Subspecialty consultations for anomalies and disabilities can be arranged during this interval. If growth velocity is below expectations, endocrine evaluation is needed to identify growth hormone deficiency or hypothyroidism. Screening for glucose intolerance and hyperinsulinemia should be performed annually or biannually, depending on the degree of hyperglycemia found on initial testing. Blood counts should be performed every 1-3 mo; bone marrow aspiration and biopsy are indicated annually for leukemia and MDS surveillance by means of morphology and cytogenetics. Patients should be assessed for solid tumors at least annually. Beginning at menarche, female patients should be screened annually for gynecologic cancer. Administration of human papilloma virus quadrivalent vaccine to prevent squamous cell carcinoma is currently advised.

Hematopoietic stem cell transplantation (HSCT; see Chapter 135) is the only curative therapy for the hematologic abnormalities. Patients <10 yr old with FA who undergo transplantation using an human leukocyte antigen (HLA)–identical sibling donor have a survival rate >80%. Survival rates are lower for patients >10 yr old who are undergoing the procedure. Preparative regimens are continuously evaluated, refined, and improved worldwide. For patients who do not have an HLA–matched sibling donor, a search for a matched unrelated donor (including a search of umbilical cord blood banks) might be initiated. Because of the need for more intensive preparation regimen and the heightened graft-versus-host response in patients with FA, the survival and cure rates have not been as good as those for matched sibling donor HSCT (≈50% survival). Molecular technology has led to preimplantation genetic diagnosis on parent-derived blastomeres to find an HLA-matched sibling donor without FA.

Androgens produce a response in 50% of patients, heralded by reticulocytosis and a rise in hemoglobin within 1-2 mo. White blood cell counts may increase next, followed by platelet counts, but it may take many months to achieve the maximum response. When the response plateaus, androgen dosage can be slowly tapered but not stopped entirely. Oral oxymetholone is used most frequently once a day. The beneficial effect of adding low-dose prednisone to androgens is controversial, but when administered orally every second day, they may counter androgen-induced growth acceleration and prevent thrombocytopenic bleeding by promoting vascular stability. In many patients who are taking androgens, the disease becomes refractory as marrow failure progresses. Potential side effects include masculinization, elevated hepatic enzymes, cholestasis, peliosis hepatis, and liver tumors. Screening for these changes should be performed serially.

The potential for recombinant growth factor (cytokine) therapy for FA has not been defined. Granulocyte colony-stimulating factor (G-CSF) can usually induce an increase in the absolute neutrophil count and occasionally may boost platelet counts and hemoglobin levels. There may be a heightened risk of expansion of marrow cells with clonal cytogenetic abnormalities such as monosomy 7. Combination therapy consisting of G-CSF given subcutaneously daily or every 2 days along with erythropoietin given subcutaneously or IV 3 times/wk results in improved neutrophil counts in almost all patients and a sustained rise in platelets and hemoglobin levels in approximately one-third of patients, although most patients lose the response after 1 yr owing to progression of marrow failure.

The premise for gene therapy in FA is based on the assumption that corrected hematopoietic cells offer a growth advantage. Attempts at gene therapy have been disappointing, possibly because of the type of vector but also because of the chromosomal fragility and impaired proliferative function of the hematopoietic progenitors. Encouraging preclinical data from studies using lentiviral vectors offer hope that gene therapy will be a safe and effective treatment for FA.

Prognosis

From FA cases reported in the 1990s, the projected median survival was >30 yr of age, an improvement over that in the previous decade. Successes with HSCT have dramatically improved the outlook. Careful surveillance for known complications, especially cancer, and prompt intervention on their detection has also contributed to the improved survival.

SHWACHMAN-DIAMOND SYNDROME

Etiology and Epidemiology

Shwachman-Diamond syndrome (SDS) is inherited in an autosomal recessive manner; it occurs in all racial and ethnic groups. As FA, SDS is also a multisystem disorder. The nonhematologic manifestations are different and usually include exocrine pancreatic insufficiency and skeletal abnormalities such as metaphyseal dysplasia. There is no increased chromosomal breakage after DEB testing of SDS lymphocytes.

Pathology

The mutant gene *SBDS* maps to chromosome 7q11 and in 90% of cases is responsible for the multisystem, pleiotropic phenotype. The wild-type gene protein product is involved in ribosomal biogenesis. Pancreatic insufficiency is a result of failure of pancreatic acinar development. Fatty replacement of pancreatic tissue is prominent. Bone marrow failure is characterized by dysfunctional hematopoietic stem cells, accelerated apoptosis of marrow progenitors and a defective marrow microenvironment that does not support and maintain normal hematopoiesis.

Clinical Manifestations

Most patients with SDS have symptoms of fat malabsorption from birth that are caused by pancreatic insufficiency, but steatorrhea is not always obvious. Approximately 50% of patients appear to exhibit an improvement in pancreatic enzyme secretion as they age. The clinical picture can be dominated by complications from anemia, neutropenia, or thrombocytopenia. Bacterial and fungal infections secondary to neutropenia, neutrophil dysfunction, and immune deficiency can occur. Short stature is a consistent feature of the syndrome; most patients show normal growth velocity yet remain consistently below the 3rd percentile for height and weight. The occasional SDS adult achieves the 25th percentile for height. Although skeletal abnormalities are variable, classic findings are delayed bone maturation, metaphyseal dysplasia, short or flared ribs, and thoracic dystrophy. Some patients have hepatomegaly and elevations of liver enzymes. Most patients have dental abnormalities and poor oral health. Many have neurocognitive problems and poor social skills.

Laboratory Findings

Fatty replacement of pancreatic tissue can be visualized by CT scan or ultrasound. Fat malabsorption is proven by assay on a 72-hr stool collection. Pancreatic function tests show markedly impaired enzyme secretion, but with preservation of ductal function. Age-adjusted serum trypsinogen and isoamylase levels are reduced. Neutropenia is present in 100% of patients with SDS on at least 1 occasion. It can be chronic persistent or intermittent. It has been identified in some neonates during an episode of sepsis. Neutrophils may have a defect in mobility, migration, and chemotaxis owing to alterations in neutrophil cytoskeletal or microtubular function. Anemia, thrombocytopenia, and pancytopenia are seen in 66%, 60%, and up to 44% of cases, respectively. Pancytopenia can be severe as a result of full-blown aplastic anemia. Bone marrow biopsy specimens and aspirates usually show varying degrees of marrow hypoplasia and fat infiltration. Patients may also have B-cell defects with 1 or more of the following: low immunoglobulin G or immunoglobulin G subclasses, low percentage of circulating B lymphocytes, decreased in vitro B-cell proliferation, and lack of specific antibody production. Patients may have a low percentage of circulating T cells, subsets, or natural killer cells, and decreased in vitro T-cell proliferation.

Diagnosis

The clinical diagnosis of SDS relies on having an evidence of bone marrow dysfunction and exocrine pancreatic dysfunction. However, up to 20% of the patients may lack clear evidence of exocrine pancreatic defects at the time of diagnosis. Mutational analysis for *SBDS* is definitive in 90% of cases. Pearson syndrome (see Chapter 450), consisting of refractory sideroblastic anemia, cytoplasmic vacuolization of bone marrow precursors, lactic acidosis, exocrine pancreatic insufficiency, and a diagnostic mitochondrial DNA mutation is similar to SDS, but the clinical course, morphologic features of the bone marrow, and gene mutation are different. Also, severe anemia requiring transfusion, rather than neutropenia, is present from birth to 1 yr of age. SDS shares some manifestations with FA, such as marrow dysfunction and growth failure, but patients with SDS are readily distinguished because of pancreatic insufficiency with fat malabsorption, fatty changes within the pancreatic body that can be visualized by imaging, characteristic skeletal abnormalities not seen in FA, and a normal chromosomal breakage study with DEB.

Complications

Patients with SDS are predisposed to MDS and leukemic transformation. The crude rate of MDS or acute leukemia in patients with SDS is 8-33%. Marrow cell clonal cytogenetic abnormalities are an isolated finding, occurring in up to 41% of patients. Isochromosome 7 [i(7q)] is particularly common, suggesting that it is a fairly specific clonal marker of SDS and probably related to the presence of mutant *SBDS* on 7q11. Other clonal chromosome abnormalities include monosomy 7, i(7q) combined with monosomy 7, deletions or translocations involving part of 7q, and deletions of 20q [Del(20q)]. Although i(7q) and Del(20q) are rarely related to leukemic transformation or MDS, the prognostic significance of all marrow clonal changes requires prospective monitoring.

Treatment

Fat malabsorption responds to oral pancreatic enzyme replacement and supplemental fat-soluble vitamins, administered according to guidelines similar to those for cystic fibrosis (see Chapter 403). A long-term plan should be initiated to monitor changes in peripheral blood counts that require corrective action and to look for early evidence of malignant myeloid transformation. The latter requires serial bone marrow aspirations for smears and cytogenetics and marrow biopsy. One recommendation is to perform marrow testing every 1-2 yr and complete blood counts every 3 mo.

Daily subcutaneous G-CSF for profound neutropenia is effective in inducing a sustained increase in neutrophils. Some patients require transfusion support for management of severe anemia or thrombocytopenia. Experience with erythropoietin is limited. In some patients who received androgens plus steroids, blood counts have improved. The only curative option for severe marrow failure in SDS is allogeneic HSCT, although experience has been limited. Traditional myeloblastic HSCT resulted in treatment-related mortality in 35-50% of the patients. The risk of cardiotoxicity has been noted. Fludarabine-based protocols using reduced-intensity conditioning appear to be safer and effective for SDS HSCT.

Prognosis

The accurate life expectancy of SDS patients is unknown. Analysis of published cases revealed a median survival of 35 yr. Because the number of undiagnosed patients with mild or asymptomatic disease is unknown, the overall prognosis may be better than previously thought. Approximately 50% of patients experience spontaneous conversion from pancreatic insufficiency to pancreatic sufficiency as a result of improvement in pancreatic enzyme secretion. Enzyme replacement therapy is then no longer needed. Although all patients have some degree of hematologic cytopenia, the changes in most patients are mild to moderate and do not require therapeutic intervention. Severe neutropenia responds well to G-CSF, but there is concern that the predisposition to MDS and acute leukemia can be heightened by the agent's powerful growth stimulus on marrow cells. HSCT for severe marrow failure has produced a 50-70% survival rate, but safer protocols are being introduced. Malignant marrow transformation remains ominous.

DYSKERATOSIS CONGENITA

Etiology and Epidemiology

Dyskeratosis congenita (DC) is an inherited multisystem disorder characterized by mucocutaneous abnormalities, bone marrow failure,

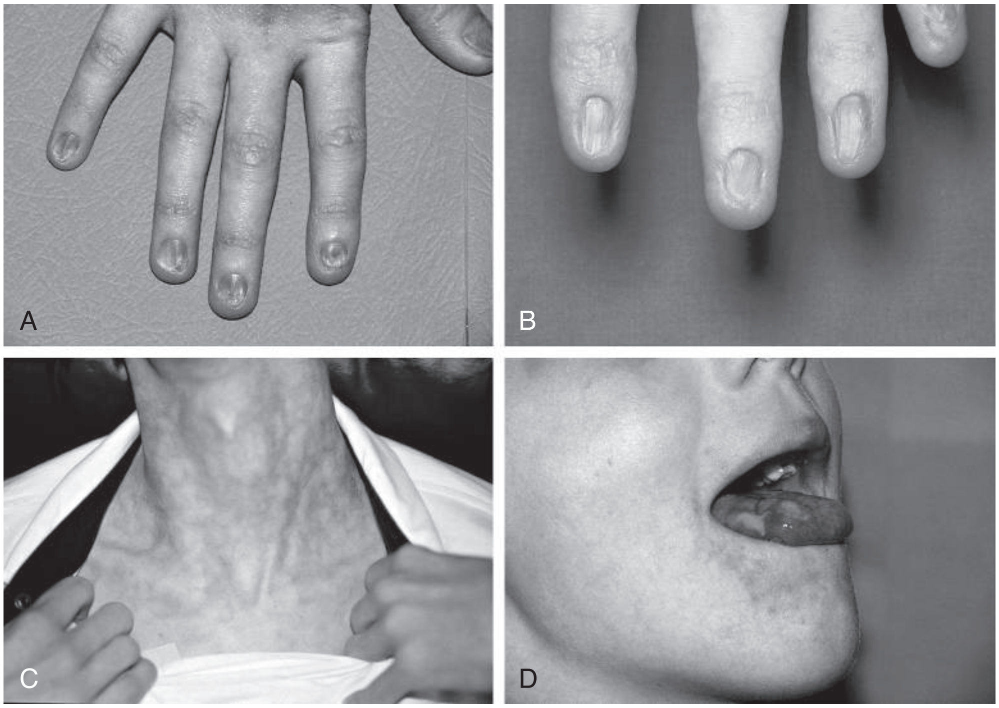

Figure 468-2 Physical findings in patients with dyskeratosis congenita. **A** and **B,** Dystrophic fingernails in 2 different patients. **C,** Lacy reticular pigmentation. **D,** Leukoplakia on the tongue. *(From Nathan DG, Orkin SH, Ginsburg D, et al, editors:* Nathan and Oski's hematology of infancy and childhood, *ed 6, vol I, Philadelphia, 2003, WB Saunders, p. 300.)*

and a predisposition to cancer and MDS. The diagnostic **mucocutaneous (ectodermal) triad** is reticulate skin pigmentation of the upper body, mucosal leukoplakia, and nail dystrophy (Fig. 468-2). Skin and nail findings usually become apparent in the 1st 10 yr of life, whereas oral leukoplakia is seen later. These manifestations tend to progress as patients get older. Varying degrees of bone marrow failure are seen in about 90% of the patients. Severe aplastic anemia occurs in approximately 50% of cases, usually in the 2nd decade of life. Many patients with DC are male, a finding compatible with the high frequency of the X-linked recessive form of the disease. The remainder have either an autosomal dominant or autosomal recessive mode of inheritance.

Pathology

DC is genetically heterogeneous, and patients have mutations in genes that encode components of the telomerase complex (*DKC1*, *TERT*, *TERC*, *NOP10*, and *NHP2*), T-loop disassembly protein (*RTEL1*), telomere capping (*CTC1*), the telomere shelterin complex (*TINF2*), and the telomerase trafficking protein (*TCAB1*), all components critical for telomere maintenance. The **X-linked recessive form** of DC maps to Xq28, and many mutations have been identified in the *DKC1* gene, which codes for the nuclear protein dyskerin. The **autosomal dominant form** is due to mutations in *TINF2,* or in *TERC* or *TERT*, the RNA and enzymatic components of telomerase, respectively. **Autosomal recessive** DC is linked to mutations in *NOP10, NHP2, RTEL1, TCAB1,* and *CTC1*. Because of impaired telomere maintenance in all 3 inherited forms of DC, short telomeres are demonstrated in the peripheral blood cells of all patients and are a cardinal marker for DC and for marrow failure. The failure is likely a result of progressive attrition and depletion of hematopoietic stem cells because of premature senescence, which manifests as pancytopenia.

Clinical Manifestations

Skin pigmentation and nail changes typically appear first, mucosal leukoplakia and excessive ocular tearing appear later, and by the mid-teens, patients with DC have bone marrow failure and malignancy. Many female patients have the same features as male patients. In males, cutaneous findings are the most consistent feature. Lacy reticulated skin pigmentation affecting the face, neck, chest, and arms is a common finding (89%). The degree of pigmentation increases with age and can involve the entire skin surface. There may also be a telangiectatic erythematous component. Nail dystrophy of both hands and feet is the next most common finding (88%). It usually starts with longitudinal ridging, splitting, or pterygium formation and may progress to complete nail loss. Leukoplakia usually involves the oral mucosa (78%), especially the tongue but may also be seen in the conjunctiva and the anal, urethral, or genital mucosa. Hyperhidrosis of the palms and soles is common, and hair loss is sometimes seen. Eye abnormalities are observed in approximately 50% of cases. Excessive tearing (epiphora) secondary to nasolacrimal duct obstruction is common. Other ophthalmologic manifestations include conjunctivitis, blepharitis, loss of eyelashes, strabismus, cataracts, and optic atrophy. An increased rate of dental decay and early loss of teeth are common. Skeletal abnormalities, such as osteoporosis, avascular necrosis, abnormal bone trabeculation, scoliosis, and mandibular hypoplasia, are seen in approximately 20% of cases. Genitourinary abnormalities include hypoplastic testes, hypospadias, phimosis, urethral stenosis, and horseshoe kidney. Gastrointestinal findings, such as esophageal strictures, vascular lesions causing bleeding, hepatomegaly, and fibrosis are seen in 10% of cases. A subset of patients has pulmonary complications, with reduced diffusion capacity and/or a restrictive defect. In fatal cases, lung tissue shows pulmonary fibrosis and abnormalities of the pulmonary vasculature.

Laboratory Findings

The initial hematologic change in DC is usually thrombocytopenia, anemia, or both, followed by full-blown pancytopenia and aplastic anemia. The red cells are often macrocytic, and the fetal hemoglobin value can be elevated initially. Initial bone marrow specimens may be hypercellular, but with time, a symmetric depletion of all hematopoietic lineages ensues. Some patients have immunologic abnormalities, including reduced or elevated immunoglobulin values, decreased B- and/or T-lymphocyte count, and reduction of or absence of lymphocyte proliferative responses to phytohemagglutinin. This is particularly common and severe in the DKC1-associated disease. Primary skin

fibroblasts in culture have abnormal morphologic features and doubling rate and show numerous unbalanced chromosome rearrangements, such as dicentrics, tricentrics, and translocations, in the absence of DEB. These findings provide evidence of a defect that predisposes patient cells to chromosomal rearrangements and possibly to DNA damage.

Diagnosis

The following abnormalities are seen in patients with DC but not in those with FA: nail dystrophy, leukoplakia, and tooth abnormalities, hyperhidrosis of the palms and soles, and hair loss (see Table 468-2). There are overlap syndromes that share some of the features of DC. **Hoyeraal-Hreidarsson syndrome** is a multisystem disorder comprising aplastic anemia, immunodeficiency, microcephaly, growth retardation, and cerebellar hypoplasia. The syndrome is genetically heterogeneous; some cases are X-linked recessive and caused by mutations in *DKC1*, and others are autosomal recessive owing to homozygous *TERT* mutations. **Revesz syndrome** consists of dystrophic nails, leukoplakia, aplastic anemia, cerebellar hypoplasia, growth retardation, microcephaly, and bilateral exudative retinopathy. *TINF2* is mutated in Revesz syndrome, which hence is an autosomal dominant variant of DC. Coats' plus syndrome is caused by mutations in the *CTC1* gene. It is characterized by retinal telangiectasia and exudates, intracranial calcification, leukodystrophy, brain cysts, osteopenia, gastrointestinal bleeding and portal hypertension caused by the development of vasculature ectasias in the stomach, small intestine and liver. Some patients with this disease has the additional manifestations of DC, which include sparse and graying hair, dystrophic nails, and anemia. Telomeres are short.

Complications

Cancer develops in approximately 10-15% of patients with DC, usually in the 3rd and 4th decades of life. Patients with DC are predisposed to MDS as well as to solid tumors. Forty percent of the cancers in such patients are squamous cell carcinomas of the head and neck (tongue, mouth, pharynx). Cancer of the skin and gastrointestinal tract (esophagus, stomach, colon, and especially the anorectal site) is also common. Other life-threatening complications include pulmonary fibrosis and severe gastrointestinal bleeding.

Treatment

Androgens (with or without low-dose prednisone) can induce improvement of marrow function in approximately 50% of patients. When the response is maximal, the androgen dose can be slowly tapered but not stopped. DC can become refractory to androgens as the aplastic anemia progresses. There is no published information on the use of immunosuppressive therapy for this disorder, but the authors are aware of several patients who were misdiagnosed with acquired aplastic anemia and treated with immunosuppressive therapy without response. Although reports are scanty, cytokine therapy with granulocyte-macrophage colony-stimulating factor or with G-CSF alone or combined with erythropoietin appears to offer potential benefit, at least in the short term, especially for improving neutrophil numbers.

Allogeneic HSCT has been used to correct marrow failure in patients with DC, long-term survival is only 50%. Vascular lesions and fibrosis involving various organs are not prevented by HSCT and can occur early and late after transplantation; carrying a high mortality rate. Patients with DC may be more susceptible to endothelial damage that occurs after HSCT as a result of various factors, including the conditioning regimen, infectious disease, and graft-versus-host disease. Up to 40% of patients with DC experience fatal pulmonary complications after transplantation.

Prognosis

Considerable heterogeneity exists in DC. Patients with certain genetic groups (e.g., *TERC* and *TERT*) have milder clinical manifestations. Patients with other genetic groups (e.g., *DKC1*, *TINF2* and *RTEL1*) appear to have more physical anomalies and a higher incidence of aplastic anemia and cancer. The mean age of death for patients with DC who are diagnosed in childhood is approximately 30 yr. The main causes of death are bone marrow failure, complications of HSCT, cancer, fatal pulmonary problems, and gastrointestinal bleeding.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA

Etiology and Epidemiology

Congenital amegakaryocytic thrombocytopenia (CAMT) is the rarest of the 4 major inherited pancytopenias. It is transmitted in an autosomal recessive manner. CAMT manifests in infancy as isolated thrombocytopenia as a result of reduction or absence of marrow megakaryocytes with initial preservation of granulopoietic and erythroid lineages. Pancytopenia caused by aplastic anemia often ensues in the first few years of life. The defect in CAMT is directly related to mutations in *MPL,* the gene for the receptor of thrombopoietin, the growth factor that promotes hematopoietic stem cell survival and stimulates megakaryocyte proliferation and maturation. Carriers of the mutant gene have normal hematology; affected individuals have mutations in both alleles. Genotype–phenotype correlations predict disease course and prognosis. **Nonsense mutations** cause a complete loss of function of the thrombopoietin receptor, causing persistently low platelet counts because of the absence of megakaryocytes and a fast progression to pancytopenia and aplastic anemia (CAMT type I). Because thrombopoietin also has an antiapoptotic and cell survival effect on stem cells, impaired stem cell survival with *MPL* nonsense mutations explains the evolution of CAMT into aplastic anemia. **Missense mutations** of *MPL* are associated with a milder course, a transient increase in platelets during the 1st yr of life, and delayed onset, if any, of pancytopenia, indicating residual receptor function (CAMT type II). Biologically active plasma thrombopoietin is consistently elevated in all patients with CAMT.

Clinical Manifestations

Patients with CAMT have petechial rash, bruising, or bleeding at birth or in the 1st yr of life. Most, but not all, patients with proven *MPL* mutations have normal physical and imaging features. Approximately 20% of published phenotypic CAMT cases involved physical anomalies, but *MPL* mutation analyses were not available in all cases. The most common anomalies in the published cases are neurologic and cardiac. Findings related to cerebellar and cerebral atrophy are frequent, and developmental delay is a prominent feature. Congenital heart disease includes atrial septal defects, ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these occur in combinations. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate. Some patients have microcephaly and an abnormal facies.

Laboratory Findings

Thrombocytopenia is the major laboratory finding in CAMT, with normal hemoglobin levels and white blood cell counts initially. Peripheral blood platelets are reduced or totally absent. As in other inherited bone marrow failure syndromes, red blood cells may be macrocytic. Hemoglobin F may be elevated, and there may be increased expression of i antigen. Initial bone marrow aspirates and biopsy specimens show normal cellularity with marked reduction or absence of megakaryocytes. In patients in whom aplastic anemia develops, marrow cellularity is decreased, with fatty replacement; erythropoietic and granulopoietic lineages are also symmetrically reduced.

Diagnosis

If thrombocytopenia persists beyond the neonatal period or is associated with adequate platelet transfusion response and no obvious precipitating cause such as infections or immunologic reactions, a marrow aspirate and biopsy is indicated. Deficient megakaryocytes in such cases suggest the diagnosis, and mutational analysis will confirm it. If CAMT occurs at birth or shortly after, it must be distinguished from other causes of inherited and acquired neonatal thrombocytopenia (see Chapter 484.8). Thrombocytopenia with absent radii (TAR syndrome) is distinguished from CAMT because in TAR syndrome the

radii are absent. The distinction from DC may be evident by mucocutaneous, neurologic, and immunologic findings that are characteristic to the early onset DC. CAMT blood lymphocytes do not show increased chromosomal breakage when exposed to DEB, distinguishing the disease it from FA.

Complications

In some patients, clonal marrow cell cytogenetic abnormalities appear such as monosomy 7 and trisomy 8. CAMT can evolve into MDS and also acute leukemia, but the true risk cannot be defined because of the rarity of the disease and the paucity of published data.

Therapy and Prognosis

The mortality rate in patients with *MPL* **nonsense** mutations from thrombocytopenic bleeding, complications of aplastic anemia, or leukemic transformation has been very close to 100%. Patients with **missense** mutations have a milder course but may still have serious complications. HSCT is the only curative option. The majority of patients with CAMT who undergo HSCT are cured, especially if the procedure is performed with HLA-matched sibling donors. Before transplantation, platelet transfusion should be used discretely. Platelet count should not always be the sole indication; clinical bleeding is an appropriate trigger. Single-donor filtered platelets are preferred to minimize sensitization. Leukodepleted platelet units might be adequate, but further studies are necessary to support such an alternative. In a patient for whom HSCT is a possibility, all blood products should be free of cytomegalovirus. Corticosteroids are not effective for treatment of the thrombocytopenia. For aplastic anemia, androgens may induce a temporary partial improvement. Interleukin-3 may be an important adjunct to the medical management of CAMT, but it was not adopted broadly and is no longer available. The role of thrombomimetic agents has to be studied; however, the induction of fibrosis by these agents and the risk of MDS/leukemia in CAMT render HSCT the preferred treatment for patients with severe cytopenia.

OTHER INHERITED SYNDROMES

Pancytopenia and bone marrow failure can occur in the context of several non-hematologic syndromes and familial settings that do not exactly correspond to the entities already described.

Down Syndrome

Down syndrome (trisomy 21; see Chapter 81.2) has a unique association with aberrant hematologic findings. In addition to the propensity for acute lymphoblastic and myeloblastic leukemias, especially acute megakaryoblastic leukemia, at least 6 patients with Down syndrome have been reported as having pancytopenia caused by aplastic anemia.

Dubowitz Syndrome

Dubowitz syndrome is an autosomal recessive disorder characterized by a peculiar facies, infantile eczema, small stature, and mild microcephaly. The face is small, with a shallow supraorbital ridge, a nasal bridge at the same level as the forehead, short palpebral fissures, variable ptosis, and micrognathia. There is a predilection to cancer as well as to bone marrow dysfunction in these patients. Approximately 10% of patients have hematopoietic disorders including moderate pancytopenia, hypoplastic anemia, bone marrow hypoplasia, and full-blown aplastic anemia. No gene mutation has been identified.

Seckel Syndrome

Seckel (SCKL) syndrome, sometimes called "bird-headed dwarfism," is an autosomal recessive developmental disorder characterized by marked growth failure and mental deficiency, microcephaly, a hypoplastic face with a prominent nose, and low-set and/or malformed ears. Approximately 25% of patients have aplastic anemia or malignancies. There is broad genetic heterogeneity comprising 7 classifiable types: SCKL1, *ATR* mutation; SCKL2, *RBBP8* mutation; SCKL3, maps to 14q21-q22; SCKL4, *CENPJ* mutation; SCKL5, *CEP152* mutation; SCKL6, *CEP63* mutation; and, SCKL7, *NIN* mutation.

Reticular Dysgenesis

Reticular dysgenesis (see Chapter 126) is an immunologic deficiency syndrome coupled with congenital agranulocytosis. The mode of inheritance autosomal recessive in some cases; there is evidence that reticular dysgenesis is caused by homozygous or compound heterozygous mutation in the mitochondrial adenylate kinase-2 gene *AK2* on chromosome 1p35 but an X-linked mode is also possible in some cases. The disorder is a variant of severe combined immune deficiency in which cellular and humoral immunity are absent and severe lymphopenia and neutropenia are also seen. Anemia and thrombocytopenia may also be present. Bone marrow specimens are hypocellular, with markedly reduced myeloid and lymphoid elements. The only curative therapy is HSCT.

Schimke Immunoosseous Dysplasia

Schimke immunoosseous dysplasia is an autosomal recessive disorder caused by mutations in the chromatin remodeling protein *SMARCAL1*. Patients have spondyloepiphyseal dysplasia with exaggerated lumbar lordosis and a protruding abdomen. There are pigmentary skin changes and abnormally discolored and configured teeth. Renal dysfunction can be problematic, with proteinuria and nephrotic syndrome. Approximately 50% of patients have hypothyroidism, 50% have cerebral ischemia, and 10% have bone marrow failure with neutropenia, thrombocytopenia, and anemia, and about 5% are predisposed to non-Hodgkin lymphoma. Lymphopenia and altered cellular immunity are present in almost all patients. In 2 published case reports, 2 patients underwent successful bone marrow transplantation.

Noonan Syndrome

Noonan syndrome is a developmental disorder characterized by the "Noonan facies" (hypertelorism, ptosis, short neck, low-set ears), short stature, congenital heart disease, and multiple skeletal and hematologic abnormalities. It is primarily an autosomal dominant disorder composed of at least 7 genetic types. Heterozygous mutations in *PTPN11* cause approximately 50% of cases of the syndrome; others are caused by mutations in *NF1, KRAS, SOS1*, *RAF1, NRAS,* or *BRAF*. Autosomal recessive forms have also been identified due to a mutation of *SHOC2* or of *CBL*. In addition to an association with juvenile myelomonocytic leukemia, Noonan syndrome patients can develop amegakaryocytic thrombocytopenia as well as pancytopenia with a hypocellular marrow.

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia, an autosomal recessive syndrome seen mostly in Finnish or Amish populations, is characterized by metaphyseal dysostosis, short-limbed dwarfism, and fine, sparse hair. Additional skeletal findings are scoliosis, lordosis, chest deformity, and varus lower limbs. Gastrointestinal abnormalities also occur. Mutations in the *RMRP* gene cause cartilage-hair hypoplasia. Macrocytic anemia is seen in most patients and is sometimes severe and persistent. Neutropenia, lymphopenia, and a predisposition to lymphoma and other cancers are also features.

UNCLASSIFIED INHERITED BONE MARROW FAILURE SYNDROMES

Unclassified inherited bone marrow failure syndromes are heterogeneous disorders that may be either atypical presentations of identifiable diseases or new syndromes. Characterized by various cytopenias because of underproductive bone marrow with or without physical manifestations, they do not fit into a classic genetic bone marrow failure disease because all features may not be evident at the time of presentation. Compared with classic disorders (presentation ≈1 mo of age), infants with unclassified disorders present later (≈9 mo) and manifest single or multilineage cytopenia, aplastic anemia, myelodysplasia, or malignancy with variable expression of malformations. Table 468-4 lists the criteria for the diagnosis. With follow-up, some may demonstrate typical physical features of known syndromes, such as SDS, although without obvious mutations in the *SBDS* gene.

Table 468-4	Canadian Inherited Marrow Failure Registry Criteria for Unclassified Inherited Bone Marrow Failure Syndromes

FULFILLS CRITERIA 1 AND 2:
1. Does not fulfill criteria for any categorized inherited bone marrow failure syndrome*
2. Fulfills both of the following

FULFILLS AT LEAST 2 OF THE FOLLOWING:
a. Chronic cytopenia(s) detected on at least 2 occasions over at least 3 mo†
b. Reduced marrow progenitors or reduced clonogenic potential of hematopoietic progenitor cells or evidence of ineffective hematopoiesis‡
c. High fetal hemoglobin for age‡
d. Red blood cell macrocytosis (not caused by hemolysis or a nutritional deficiency)

FULFILLS AT LEAST 1 OF THE FOLLOWING:
a. Family history of bone marrow failure
b. Presentation at age <1 yr
c. Anomalies involving multiple systems to suggest an inherited syndrome

*The Canadian Inherited Marrow Failure Registry diagnostic guidelines for selected syndromes were adapted from the literature and are available at http://www.sickkids.ca/cimfr.

†Cytopenia was defined as follows: neutropenia, neutrophil count of $<1.5 \times 10^9$/L; thrombocytopenia, platelet count of $<150 \times 10^9$/L; anemia, hemoglobin concentration of <2 standard deviations below mean, adjusted for age.

‡Hemoglobinopathies with ineffective erythropoiesis and high hemoglobin F should be excluded by clinical or laboratory testing.

Familial cases with aplastic anemia that cannot be readily classified into discrete diagnostic entities such as FA have been reported. When the patients present not early after birth and without physical malformations an acquired etiology cannot be ruled out. Detailed genetic testing for known inherited bone marrow failure syndrome genes or by whole exome or genome sequencing may identify an inherited etiology.

Chapter 469

The Acquired Pancytopenias

Jeffrey D. Hord

ETIOLOGY AND EPIDEMIOLOGY

Drugs, chemicals, toxins, infectious agents, radiation, and immune disorders can result in pancytopenia by direct destruction of hematopoietic progenitors, disruption of the marrow microenvironment, or immune-mediated suppression of marrow elements (Table 469-1). A careful history of exposure to known risk factors should be obtained for every child presenting with pancytopenia. Even in the absence of the classic associated physical findings, the possibility of a genetic predisposition to bone marrow failure should always be considered (see Chapter 468). The majority of cases of acquired marrow failure in childhood are "idiopathic," in that no causative agent is identified. Many are probably immune-mediated through activated T lymphocytes and cytokine destruction of marrow progenitor cells. The overall incidence of acquired aplastic anemia is relatively low, with an approximate incidence in both children and adults in the United States and Europe of 2-6 cases/million population/yr. The incidence is higher in Asia, with as many as 14 cases/million population/yr in Japan.

Table 469-1 Etiology of Acquired Aplastic Anemia
Radiation, drugs, and chemicals:
Predictable: chemotherapy, benzene
Idiosyncratic: chloramphenicol, antiepileptics, gold; 3,4-methylenedioxymethamphetamine
Viruses:
Cytomegalovirus
Epstein-Barr
Hepatitis B
Hepatitis C
Hepatitis non-A, non-B, non-C (seronegative hepatitis)
HIV
Immune diseases:
Eosinophilic fasciitis
Hypoimmunoglobulinemia
Thymoma
Pregnancy
Paroxysmal nocturnal hemoglobinuria
Marrow replacement:
Leukemia
Myelodysplasia
Myelofibrosis
Autoimmune
Other:
Cryptic dyskeratosis congenita (no physical stigmata)
Telomerase reverse transcriptase haploinsufficiency

Severe bone marrow suppression can develop after exposure to many different drugs and chemicals, including certain chemotherapeutic agents, insecticides, antibiotics, anticonvulsants, nonsteroidal antiinflammatory agents, and recreational drugs. Some of the most notable agents are benzene, chloramphenicol, gold, and, 3,4,-methylenedioxymethamphetamine (Ecstasy).

A number of viruses can either directly or indirectly result in bone marrow failure. Parvovirus B19 is classically associated with isolated red blood cell aplasia, but in patients with sickle cell disease or immunodeficiency, it can result in transient pancytopenia (see Chapter 251). Prolonged pancytopenia can occur after infection with many of the hepatitis viruses, herpes viruses, Epstein-Barr virus (see Chapter 254), cytomegalovirus (see Chapter 255), and HIV (see Chapter 276).

Patients with evidence of bone marrow failure should also be evaluated for inherited forms of marrow failure, paroxysmal nocturnal hemoglobinuria (PNH; see Chapter 464), and collagen vascular diseases. Pancytopenia without peripheral blasts may be caused by bone marrow replacement by leukemic blasts or neuroblastoma cells.

PATHOLOGY AND PATHOGENESIS

The hallmark of aplastic anemia is peripheral pancytopenia, coupled with hypoplastic or aplastic bone marrow. The severity of the clinical course is related to the degree of myelosuppression. **Severe aplastic anemia** is defined as a condition in which 2 or more cell components have become seriously compromised (absolute neutrophil count <500/mm^3, platelet count <20,000/mm^3, reticulocyte count <1% after correction for hematocrit) in a patient whose bone marrow biopsy material is moderately or severely hypocellular. Approximately 65% of patients who first present with **moderate aplastic anemia** (absolute neutrophil count 500-1,500/mm^3, platelet count 20,000-100,000/mm^3, reticulocyte count <1%) eventually progress to meet the criteria for severe disease, if they are simply observed. Bone marrow failure may be a consequence of a direct cytotoxic effect on hematopoietic stem cells from a drug or chemical or may result from either cell-mediated or antibody-dependent cytotoxicity. There is strong evidence that many cases of idiopathic aplastic anemia are caused by an immune-mediated process, with increased circulating activated T lymphocytes producing cytokines (interferon-γ) that suppress hematopoiesis. Abnormal telomere

length and telomerase activity in granulocytic precursors and increased expression of cell surface Flt3 ligand (a member of the class III receptor tyrosine kinase family) in the lymphocytes of patients with aplastic anemia suggest that early apoptosis of hematopoietic progenitors may play a role in the pathogenesis of this disease.

CLINICAL MANIFESTATIONS, LABORATORY FINDINGS, AND DIFFERENTIAL DIAGNOSIS

Pancytopenia results in increased risks of cardiac failure, infection, bleeding, and fatigue. Acquired pancytopenia is typically characterized by anemia, leukopenia, and thrombocytopenia in the setting of elevated serum cytokine values. Other treatable disorders, such as cancer, collagen vascular disorders, PNH, and infections that may respond to specific therapies (IV immune globulin for parvovirus), should be considered in the differential diagnosis. Careful examination of the peripheral blood smear for red blood cell, leukocyte, and platelet morphologic features is important. A reticulocyte count should be performed to assess erythropoietic activity. In children, the possibility of congenital pancytopenia must always be considered, and chromosomal breakage analysis should be performed to evaluate for Fanconi anemia (see Chapter 468). The presence of fetal hemoglobin suggests congenital pancytopenia but is not diagnostic. To assess for the possibility of PNH, flow cytometric analysis of erythrocytes for CD55 and CD59 is the most sensitive test. Bone marrow examination should include both aspiration and a biopsy, and the marrow should be carefully evaluated for morphologic features, cellularity, and cytogenetic abnormalities.

TREATMENT

The treatment of children with acquired pancytopenia requires comprehensive supportive care coupled with an attempt to treat the underlying marrow failure. For patients with an human leukocyte antigen–identical family member donor, allogeneic hematopoietic stem cell transplantation (HSCT) offers a 90% chance of long-term survival. The typical preparative regimen today consists of cyclophosphamide, fludarabine, and horse antithymocyte globulin (ATG). The risks associated with this approach include the immediate complications of transplantation, graft failure, and graft versus host disease. Late adverse effects associated with transplantation may include secondary cancers, cataracts, short stature, hypothyroidism, and gonadal dysfunction (see Chapters 136-139). Only 1 in 5 patients has a human leukocyte antigen–matched sibling donor, so matched-related HSCT is not an option for the majority of patients.

For patients without a sibling donor, the major form of therapy is immunosuppression with horse ATG and cyclosporine, with a response rate of 70-80%. The median time to response is 6 mo. As many as 30% of responders experience relapse after discontinuation of immunosuppression, and some patients must continue cyclosporine for several years to maintain a hematologic response. Among those who relapse after immunosuppression, approximately 50% show response to a second course of ATG and cyclosporine. There is an increased risk (<10%) of clonal bone marrow disease, such as leukemia, myelodysplasia (MDS), or PNH after immunosuppression with karyotypic abnormalities most frequently involving chromosomes 6, 7, and 8. To accelerate neutrophil recovery, a hematopoietic colony-stimulating factor (e.g., granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor) is sometimes added to ATG and cyclosporine for treatment of patients with very severe neutropenia (absolute neutrophil count <200/mm^3), but there is no clear evidence that this treatment influences response rate or survival. In a few cases, tacrolimus has been given successfully with ATG for treatment of aplastic anemia in patients unable to tolerate cyclosporine. Higher baseline reticulocyte count correlates with a higher probability of response to immunosuppression and survival. There is an inverse correlation between telomere length and the probability of relapse post-immunosuppression.

For patients who show no response to immunosuppression or who experience relapse after immunosuppression, matched unrelated HSCT and T-cell depleted haploidentical family member donor HSCT are treatment options, with a response rate approaching 90%. Cord blood transplants have been carried out in this refractory group of patients but there is a significant incidence of non-engraftment. High-dose cyclophosphamide has been used successfully in the treatment of patients with newly diagnosed aplastic anemia and in patients without adequate response to immunosuppression. This therapy leads to prolonged severe pancytopenia, increasing the risk of life-threatening infection, especially fungal. Other therapies that have been used in the past with inconsistent results include androgens, corticosteroids, and plasmapheresis. However, preliminary studies with eltrombopag (an oral thrombopoietin mimetic agent) have resulted in a hematologic response with improvements in platelet and neutrophil counts and hemoglobin levels in some patients. In patients who responded, bone marrow biopsies demonstrated trilineage normalization of hematopoiesis; some who were dependent on platelet or erythrocyte transfusions no longer needed transfusions.

COMPLICATIONS

The major complications of severe pancytopenia are predominantly related to the risk of life-threatening bleeding from prolonged thrombocytopenia or to infection secondary to protracted neutropenia. Patients with protracted neutropenia as a result of bone marrow failure are at risk not only for serious bacterial infections but also for invasive mycoses. Patients who have been transfused with red blood cells regularly over a long period are at increased risk of developing alloantibodies to red cell antigens and may require iron chelation therapy for transfusional iron overload. The general principles of supportive care that have evolved from the use of chemotherapy-related myelosuppression to treat patients with cancer should be fully extended to the care of patients with acquired pancytopenia.

PROGNOSIS

Spontaneous recovery from pancytopenia rarely occurs. If left untreated, severe pancytopenia has an overall mortality rate of approximately 50% within 6 mo of diagnosis and of >75% overall, with infection and hemorrhage being the major causes of morbidity and mortality. The majority of children with acquired severe aplastic anemia show response to allogeneic marrow transplantation or immunosuppression, leaving them with normal or near-normal blood cell counts.

PANCYTOPENIA CAUSED BY MARROW REPLACEMENT

Processes that either infiltrate or replace the bone marrow can manifest as acquired pancytopenia. Infiltration can be caused by malignancy (classically, neuroblastoma or leukemia) or occur as a consequence of myelofibrosis, MDS, or osteoporosis. Although uncommon, evidence of hypoplastic anemia can precede the onset of acute leukemia, generally by a few months. This relationship is important to appreciate in evaluating and monitoring children who present with what appears to be acquired aplastic anemia. Morphologic examination of the peripheral blood and bone marrow and marrow cytogenetic studies are critically important in making the diagnoses of leukemia, myelofibrosis, and MDS.

MDS is very rare in children, but when it occurs, its clinical course is more aggressive than the same category of MDS in adults. Pediatric MDS can be subdivided into refractory cytopenia of childhood (peripheral blasts <2% and marrow blasts <5%), refractory anemia with excess blasts (peripheral blasts 2-19% and/or marrow blasts 5-19%), and refractory anemia with excess blasts in transformation (peripheral and/or marrow blasts 20-29%). Disease in children with >30% blasts is usually defined as acute myelocytic leukemia.

A number of inherited conditions are associated with an increased risk for development of MDS, including Down syndrome, severe congenital neutropenia, Noonan syndrome, Fanconi anemia, trisomy 8 mosaicism, neurofibromatosis, and Shwachman syndrome. Significant clonal abnormalities are found within the marrow of approximately 50% of patients with MDS, with monosomy 7 and being most common but prognostically neutral. Those with a structurally complex karyotype have a very poor outcome.

The transition time from pediatric MDS to acute leukemia is relatively short, at 14-26 mo, so aggressive treatment, such as HSCT, must be considered shortly after diagnosis. With allogeneic HSCT, the survival rate is approximately 60%. One exception to such an aggressive therapeutic approach is MDS and acute myelocytic leukemia in children with Down syndrome, because this disease in this specific population is very responsive to conventional chemotherapy, with long-term survival rates >80%.

The decision on how to treat a child with MDS who lacks a suitable hematopoietic stem cell donor should be made with the specific clonal abnormality found within the child's marrow taken into consideration. Lenalidomide produces the best responses among patients who have the chromosomal abnormality, 5q−. Immunosuppressive therapy with ATG and cyclosporine is most effective in patients with trisomy 8, especially in the presence of a PNH clone. Imatinib mesylate targets mutations in the tyrosine kinase receptor family of genes found in patients with t(5;12) and del(4q12). The DNA hypomethylating agents azacitidine and decitabine have also been used in treating MDS without a known molecular target and have some effect.

Section 6
Blood Component Transfusions

Chapter 470
Red Blood Cell Transfusions and Erythropoietin Therapy
Ronald G. Strauss

Red blood cells (RBCs) are transfused to increase the oxygen-carrying capacity of the blood, with the goal to increase or maintain satisfactory tissue oxygenation; this goal may not be achieved simply by increasing the blood hemoglobin concentration or hematocrit by an RBC transfusion because tissue oxygenation depends on several additional factors including oxygen off-loading from RBCs, microvascular blood flow, and diffusion of oxygen into tissue cells. Although some attempts have been made to accurately relate posttransfusion blood hemoglobin concentration or hematocrit values to changes in posttransfusion tissue oxygenation (e.g., improvements in the ratio of cerebral versus mesenteric oxygenation patterns assessed by serial near-infrared spectroscopy measurements), decisions to transfuse RBCs per physiologic indications, rather than degree of anemia, remain investigational.

Because neonates, especially extremely low birthweight preterms are not "small" children (i.e., RBC physiology and the pathophysiology of the anemia of prematurity are unique), RBC transfusions for neonates and older children will be considered separately. Guidelines for RBC transfusions in children and adolescents are based on maintaining a specified hemoglobin or hematocrit level considered to be optimal (per the best evidence available) for the clinical condition present at the time of the transfusion. The guidelines are similar to those for adults (Table 470-1). Transfusions may be given more stringently to children, because normal hemoglobin levels are lower in healthy children than in adults and, as is often the case, children do not have the underlying multiorgan, cardiorespiratory, and vascular diseases that develop with aging in adults to suggest a need for RBC transfusions Thus, children may compensate better for RBC loss than elderly adults and, as is true for patients of all ages, there is increasing enthusiasm for applying conservative practices (i.e., accept lower pretransfusion hematocrit values to "trigger" a RBC transfusion).

In the perioperative period, it is unnecessary for most children to maintain hemoglobin levels of 8 g/dL or greater, a level frequently desired for adults. The desired preoperative hemoglobin level should take into account the estimated blood loss for the surgical procedure planned and the rate of bleeding. There should be a compelling reason to prescribe any postoperative RBC transfusion, such as continued bleeding with hemodynamic instability, because most children (without continued bleeding) can, in a relatively short time, restore their RBC mass with iron therapy. The most important measures in the treatments of acute hemorrhage are to control the hemorrhage and, if blood loss is modest, to restore the circulating blood volume and tissue perfusion with crystalloid or, less often, colloid solutions. If the estimated blood loss is >25% of the circulating blood volume (>15 mL/kg of an estimated 60 mL/kg total estimated blood volume) *and* the patient's condition is unstable despite intravenous fluids, RBC transfusions may be indicated; given with plasma transfusions at a 1 : 1 ratio of RBC : plasma volumes. Details of combined RBC and plasma transfusions, the volume ratio transfused, and considerations for adding platelet transfusions to treat bleeding patients are controversial. Accordingly, each hospital should develop and follow a "massive transfusion" protocol to ensure consistent practices.

In critically ill children with severe cardiac or pulmonary disease requiring assisted ventilation, it is common practice to maintain the hemoglobin level close to the normal range, although the efficacy of this practice has not been well documented. A similar approach is used for children with acute cardiac, pulmonary, or cardiopulmonary disorders managed with extracorporeal membrane oxygenation.

The pretransfusion blood hemoglobin level or hematocrit that should "trigger" a RBC transfusion is controversial (i.e., restrictive or a low pretransfusion level vs. liberal or a high pretransfusion level)

Table 470-1 Guidelines for Pediatric Red Blood Cell Transfusions*†

CHILDREN AND ADOLESCENTS
1. Maintain stable status with acute loss of >25% of circulating blood volume
2. Maintain hemoglobin >7.0 g/dL† in the perioperative period
3. Maintain hemoglobin >12.0 g/dL with *severe* cardiopulmonary disease
4. Maintain hemoglobin >12.0 g/dL during extracorporeal membrane oxygenation
5. Maintain hemoglobin >7.0 g/dL and *symptomatic* chronic anemia
6. Maintain hemoglobin >7.0 g/dL and *marrow failure*
INFANTS ≤4 MO OLD
1. Maintain hemoglobin >12.0 g/dL and *severe* pulmonary disease
2. Maintain hemoglobin >12.0 g/dL during extracorporeal membrane oxygenation
3. Maintain hemoglobin >10.0 g/dL and *moderate* pulmonary disease
4. Maintain hemoglobin >12.0 g/dL and *severe* cardiac disease
5. Maintain hemoglobin >10.0 g/dL preoperatively and during *major* surgery
6. Maintain hemoglobin >7.0 g/dL postoperatively
7. Maintain hemoglobin >7.0 g/dL and *symptomatic* anemia

*Words in *italics* must be defined for local transfusion guidelines.
†Pretransfusion blood hemoglobin level (convert to hematocrit values if preferred by multiplying hemoglobin values by 3) "triggering" an RBC transfusion. Hemoglobin values to maintain vary among published reports, and the guideline values to maintain should be determined locally to fit the practices judged to be optimal by local MDs.

despite a substantial amount of published information, including randomized clinical trials. The current trend in critical care settings is to transfuse RBCs quite conservatively, following restrictive guidelines, and to permit modest anemia because there appears to be no disadvantage to conservative/restrictive transfusion practices, and some patients with hemoglobin levels maintained close to the normal range by RBC transfusions (i.e., liberal guidelines) have poorer outcomes. Studies in critically ill adults demonstrated better outcomes when the hemoglobin level was maintained at 7-9 g/dL versus 10-12 g/dL. Anemic adults with significant cardiac disease did better with hemoglobin levels maintained at 13 g/dL than at 10 g/dL. Similar studies in children admitted to intensive care units found no inferiority when RBC transfusions were given by restrictive guidelines (transfusion threshold of 7 g/dL). It must be remembered that the children studied were in stable clinical status and needed few transfusions. Therefore, results of the trial cannot be automatically extended to all patients admitted to intensive care units, as unstable critically ill children, who were not studied, may need more liberal RBC transfusions.

With chronic anemia, the decision to transfuse RBCs should not be based solely on blood hemoglobin levels, because children compensate well and may be asymptomatic despite low hemoglobin levels. Patients with iron-deficiency anemia are often treated successfully with oral iron alone, even at hemoglobin levels <5 g/dL. Factors other than hemoglobin concentration to be considered in the decision to transfuse RBCs include: (1) the patient's symptoms, signs, and compensatory capacities; (2) the presence of underlying cardiorespiratory, vascular, and central nervous system disease; (3) the cause and anticipated course of the anemia; and (4) alternative therapies, such as recombinant human erythropoietin (EPO) therapy, which is known to reduce the need for RBC transfusions and to improve the overall condition of children with chronic renal insufficiency (see Chapter 535.2). In anemias that are likely to be permanent, it is also important to balance the detrimental effects of the degree of long-standing anemia on growth and development against the potential toxicity associated with repeated transfusions given to maintain the blood hemoglobin concentration at a specified level. RBC transfusions for disorders such as sickle cell anemia and thalassemia are discussed in Chapters 462.1 and 462.9.

For neonates, nearly all aspects of RBC transfusions remain controversial (i.e., the accepted indications for RBC transfusions; restrictive vs. liberal pretransfusion hemoglobin/hematocrit levels; optimal RBC product to be transfused; fresh vs. stored RBC units), and clinical practices vary greatly. Generally, RBCs are given to maintain a hemoglobin value believed to be the most desirable for each neonate's clinical status (see Table 470-1). Restrictive guidelines (i.e., lower pretransfusion hemoglobin/hematocrit levels) have been compared to more liberal transfusion practices, but both short-term and long-term results/outcomes have been inconsistent and controversial, particularly as to neurodevelopmental status, with poorer outcomes seen in both the restrictive and liberal study arms. Accordingly, conventional guidelines are recommended to avoid problems caused by either undertransfusion or overtransfusion, until more definitive data are published (see Table 470-1).

This clinical approach is imprecise, but more physiologic guidelines/indications such as measurement of RBC mass, calculations of oxygen delivery and tissue extraction, imaging of microcirculatory flow, and comparative measures of tissue perfusion (e.g., ratio of cerebral : mesenteric oxygenation patterns), are too cumbersome for day-to-day clinical practice.

During the first few weeks of life, all neonates experience a decline in circulating RBC mass caused both by physiologic factors and, in sick premature infants, by phlebotomy blood losses. In healthy term infants, the nadir hemoglobin value rarely falls to <11 g/dL at an age of 10-12 wk. This benign *physiologic anemia of infancy* does not require transfusions. In contrast, the decline occurs earlier and is more pronounced in premature infants, in whom the mean hemoglobin concentration falls to approximately 7 g/dL in infants weighing <1 kg at birth, resulting in the *anemia of prematurity*, for which there often is need for RBC transfusions.

A key reason that the nadir hemoglobin values of premature infants are lower than those of term infants is the former group's relatively diminished plasma EPO level in response to anemia (see Chapters 103.1 and 446). Another factor is the rapid disappearance of EPO from infant plasma (i.e., accelerated metabolism).

Low plasma EPO levels provide a rationale for the possible use of recombinant EPO in the treatment of anemia of prematurity; treatment with EPO and iron effectively stimulate neonatal erythropoiesis. Despite its erythropoietic effect, the efficacy of EPO therapy to substantially diminish the need for RBC transfusions has not been convincingly demonstrated, particularly for sick, extremely premature neonates, and recombinant EPO has not been widely accepted as a treatment for anemia of prematurity (see Chapter 103.1).

Because of the controversies over recombinant EPO therapy, many low birthweight preterm infants need RBC transfusions (see Table 470-1). Although the practice to maintain a very high hemoglobin level (hemoglobin >13 g/dL or hematocrit >40%) was once widely recommended, currently more restrictive guidelines have been suggested. Consistent with the rationale for oxygen delivery in neonates with severe respiratory disease, it seems appropriate to keep the hemoglobin value relatively high in neonates with *severe cardiac disease* leading to either cyanosis or congestive heart failure, but convincing and consistent data are lacking.

The optimal hemoglobin level for neonates facing major surgery has not been established. However, it seems reasonable to begin surgery in neonates with the hemoglobin level no lower than 10 g/dL (hematocrit >30%) and to maintain that value during major surgery because even modest blood loss will have a relatively large effect on the small blood volume of the neonate; neonates with underlying pulmonary problems have limited ability to compensate for anemia, and the inferior offloading of oxygen because of the diminished interaction between fetal hemoglobin and 2,3-diphosphoglycerate. Postoperatively, a lower pretransfusion hemoglobin value should be followed to "trigger" a transfusion.

Stable neonates do not require RBC transfusion, regardless of their blood hemoglobin levels, unless they exhibit clinical symptoms attributable to anemia. Proponents of RBC transfusions for symptomatic anemia in preterm neonates believe that the low RBC mass contributes to tachypnea, dyspnea, tachycardia, apnea and bradycardia, feeding difficulties, and lethargy, which can be alleviated by transfusion of RBCs. However, anemia is only one of several possible causes of these problems, and RBC transfusions should only be given when clinical benefit seems likely.

The RBC product of choice to transfuse neonates, infants, children, and adolescents is prestorage leukocyte-reduced RBCs suspended in an anticoagulant/preservative storage solution at a hematocrit value of approximately 60% for storage up to 42 days. The usual dose is 10-15 mL/kg, but transfusion volumes vary greatly, depending on clinical circumstances (continued vs. arrested bleeding, hemolysis). For neonates, some prefer a centrifuged RBC concentrate (hematocrit 70-90%). Unless transfusions are being given to treat rapid bleeding, RBCs are infused slowly (over 2-4 hr) at a dose of approximately 15 mL/kg. In this small-volume setting, because of the small quantity of extracellular fluid transfused and the slow rate of infusion, the type of RBC anticoagulant/preservative solution does not pose any risk for premature infants; there are no data to justify separate inventories of different RBC products for neonates and infants (e.g., citrate-phosphate-dextrose or citrate-phosphate-dextrose-adenine) versus older children (e.g., AS-1, AS-3, or AS-5).

The historical practice of transfusing fresh RBCs (<7 days of storage) for the small-volume (15 mL/kg) transfusions commonly given was supplanted several years ago in most centers by reserving a single unit of RBCs for an infant, from which multiple aliquots were obtained for transfusions as needed throughout the 42 days of storage. Concerns about high concentrations of extracellular potassium, loss of 2,3-diphosphoglycerate, altered RBC shape and deformability, and nitric oxide quenching were found not to pose clinically significant problems. Preterm neonates allocated to "fresh RBC" (<7 day storage) transfusions versus "stored RBC" (up to 42 day storage) transfusions,

have no advantage for fresh RBC transfusions in altering either the composite clinical outcome of mortality plus necrotizing enterocolitis, retinopathy of prematurity, bronchopulmonary dysplasia, and intraventricular hemorrhage or of the individual disorders.

For children weighing >30 kg who are to undergo elective surgery for which RBC transfusions are likely to be needed, autologous RBC transfusions offer an alternative to donor allogeneic RBCs. **Preoperative autologous** blood collections from the patient occur up to 6 wk before the surgery and require careful considerations for the volume to be drawn, vascular access, and use of EPO and iron to help restore the donated RBCs. **Acute normovolemic hemodilution** occurs in the preoperative period, in which blood is withdrawn from the patient and replaced with saline, a task often difficult in centers without experience in the process. **Salvaged autologous blood** is collected from blood loss during the operation but is impractical unless the volume of blood salvaged is fairly large to permit washing and transfusion of a significant number of RBCs. Because of all of these difficulties plus the relative safety of the usual allogeneic blood supply, autologous RBC transfusions are not commonly used in the pediatric setting.

Chapter 471

Platelet Transfusions

Ronald G. Strauss

Guidelines for platelet (PLT) support of children and adolescents with quantitative and qualitative PLT disorders are similar to those for adults (Table 471-1), in whom the risk of life-threatening bleeding after injury or occurring spontaneously can be related somewhat imprecisely, particularly for the occurrence of spontaneous bleeding to the severity of thrombocytopenia.

For children and adolescents with overt bleeding, therapeutic PLT transfusions should be given when the blood PLT count falls below 50 × 10^9/L and repeated as needed to maintain the PLT count >50 × 10^9/L during bleeding and for 48 hr after bleeding ceases to allow the clot to "stabilize." Similarly, for a major invasive procedure (e.g., surgical procedure), the PLT count should be maintained >50 × 10^9/L until any bleeding that occurs ceases and the patient is stable. For minor invasive procedures (e.g., lumbar puncture or placing an intravascular catheter) practices vary, but it is reasonable to maintain the PLT count >25 × 10^9/L.

Table 471-1	Guidelines for Pediatric Platelet Transfusion*
CHILDREN AND ADOLESCENTS	
1. Maintain PLT count >50 × 10^9/L with bleeding	
2. Maintain PLT count >50 × 10^9/L with *major invasive* procedure; >25 × 10^9/L with minor	
3. Maintain PLT count >20 × 10^9/L and *marrow failure* WITH hemorrhagic risk factors	
4. Maintain PLT count >10 × 10^9/L and *marrow failure* WITHOUT hemorrhagic risk factors	
5. Maintain PLT count at any level with PLT dysfunction PLUS bleeding or invasive procedure	
INFANTS ≤4 MO OLD	
1. Maintain PLT count >100 × 10^9/L with bleeding or during extracorporeal membrane oxygenation	
2. Maintain PLT count >50 × 10^9/L and an invasive procedure	
3. Maintain PLT count >20 × 10^9/L and *clinically stable*	
4. Maintain PLT count >50 × 10^9/L and *clinically unstable and/or bleeding or not when on indomethacin, nitric oxide, antibiotics, etc. affecting PLT function*	
5. Maintain PLT count at any level with PLT dysfunction PLUS bleeding invasive procedure	

*Words in *italics* must be defined for local transfusion guidelines.
PLT, platelet.

Historical studies of patients with thrombocytopenia resulting from bone marrow failure suggest that the risk of spontaneous bleeding increases when blood PLT levels fall to <20 × 10^9/L particularly when hemorrhagic risk factors (infection, organ failure, clotting abnormalities, minor skin/mucosal bleeding, mucosal lesions, severe graft-versus-host disease, or anemia) are present. In this high-risk setting, prophylactic PLT transfusions are given to maintain a PLT count >20 × 10^9/L. This threshold has been challenged by several studies of adult patients, who, in many instances, were carefully selected to be in relatively good clinical condition *without* hemorrhagic risk factors. Consequently, a higher PLT transfusion trigger of 50 × 10^9/L is recommended for stable (i.e., low-risk) patients.

In practice, severe thrombocytopenia that is prolonged beyond 1 wk commonly becomes complicated by the development of risk factors including fever, antimicrobial therapy, graft-versus-host disease, active bleeding, need for an invasive procedure, disseminated intravascular coagulation, and liver or kidney dysfunction with clotting abnormalities. In these situations, prophylactic PLT transfusions are given to maintain relatively high PLT counts (e.g., at least >30 × 10^9/L). Despite the desire by some physicians to elevate the blood PLT count to 80 × 10^9/L or 100 × 10^9/L, there are no definitive data to justify a true benefit of PLT transfusions given at a PLT count >50 × 10^9/L, unless bleeding is ongoing with a PLT count between 50 and 100 × 10^9/L *and* thrombocytopenia seems to be the only cause for the bleeding.

Qualitative PLT disorders may be inherited or acquired (in advanced hepatic or renal insufficiency or when blood flows through an extracorporeal circuit, such as during extracorporeal membrane oxygenation or cardiopulmonary bypass). In patients with inherited disorders, PLT transfusions are justified only if the risk of significant bleeding is quite high or if bleeding is overt because inherited PLT dysfunction often is lifelong and repeated transfusions may lead to alloimmunization and refractoriness (i.e., poor response to PLT transfusions). Accordingly, prophylactic PLT transfusions are rarely justified, unless an invasive procedure is planned, and therapeutic PLT transfusions must be given judiciously.

When managing patients with PLT dysfunction, it is important to remember that, an abnormal test result with a modern PLT function device or, historically, a bleeding time more than twice the upper limit of normal provides diagnostic evidence of PLT dysfunction. However, an abnormal bleeding time or any other abnormal laboratory test is poorly predictive of hemorrhagic risk and/or the need to transfuse PLTs. Alternative therapies, particularly desmopressin acetate, should be considered to avoid PLT transfusions. Antiplatelet medications (nonsteroidal antiinflammatory drugs) should also be avoided.

In neonates, thrombopoiesis and the risks of bleeding are substantially different from that in older children; the approach to thrombocytopenia and PLT transfusions likewise differs (see Table 471-1). Thrombopoietin (TPO) levels are higher in healthy neonates than in older individuals. Megakaryocyte progenitors of neonates are more sensitive to TPO, have higher proliferative potential, and give rise to larger megakaryocyte colonies than do adult PLT progenitors. Fetal/neonatal megakaryocytes are smaller in size and have lower ploidy than do their adult counterparts; this is an important factor because small megakaryocytes of low ploidy produce fewer PLTs than larger megakaryocytes of higher ploidy. Presumably, this allows the expanding marrow of the growing fetus and neonate to be supplied with sufficient numbers of megakaryocytes, yet not allowing blood PLT counts to become excessively high during proliferation, because of the lower numbers of PLTs produced by each megakaryocyte.

An important contrasting point is that older children and adults respond to situations of increased demand for PLTs by first increasing megakaryocyte size and ploidy, which is followed in 3-5 days by

increased megakaryocyte number. In thrombocytopenic neonates, megakaryocyte numbers increase, but not their size. Moreover, although cytoplasmic maturation is achieved per TPO stimulation, increases in ploidy are relatively diminished and actually appear to be inhibited by TPO, resulting in large numbers of small megakaryocytes that are cytoplasmically mature, but with low ploidy and, consequently, lower PLT production.

Blood PLT counts $\geq 150 \times 10^9/L$ are present after 17 wk gestational age, and it is accepted that neonates have blood PLT counts in the same range as older children and adults (150,000-450,000/μL). However, recent data suggest a lower limit of 120,000/μL for extremely small preterm infants. Approximately 1% of term infants demonstrate PLT counts $<150 \times 10^9/L$, but bleeding in such infants is rare. In contrast, 25-35% of preterm of neonates treated in intensive care units exhibit blood PLT counts $<150 \times 10^9/L$ at some time during admission, with approximately 4% overall receiving PLT transfusions. Notably, when only extremely low birthweight preterm infants (<1 kg birthweight) were considered in one report, 73% had PLT counts $<150 \times 10^9/L$ and 62% of thrombocytopenic neonates received PLT transfusions. Multiple pathogenetic mechanisms underlie thrombocytopenia in these sick neonates; predominantly accelerated PLT destruction plus diminished PLT production, as evidenced by decreased numbers of megakaryocyte progenitors and relatively low upregulation of TPO levels during thrombocytopenia, compared with thrombocytopenic children and adults.

Blood PLT counts $<100 \times 10^9/L$ pose significant clinical risks for premature neonates. Bleeding time may be prolonged at PLT counts $<100 \times 10^9/L$ in infants with a birthweight <1.5 kg, and PLT dysfunction is suggested by bleeding times (a test no longer performed) that are disproportionately long for the degree of thrombocytopenia. The risk of hemorrhage may be increased in thrombocytopenic infants. However, in a randomized trial, transfusing PLTs prophylactically whenever the PLT count fell to $<150 \times 10^9/L$ (i.e., at the lower limit of the normal range) to maintain the average PLT count at $>200 \times 10^9/L$, compared to not transfusing PLTs until the PLT count fell to $<50 \times 10^9/L$ to maintain the average PLT count at approximately $100 \times 10^9/L$, did not result in a lower incidence of intracranial hemorrhage (28% vs. 26%, respectively). Thus, there is no documented benefit for prophylactic PLT transfusions to maintain PLT counts within the normal range or to correct modest thrombocytopenia (PLT count $>50 \times 10^9/L$). As an exception, infants with inherited PLT dysfunction disorders *and* bleeding, and those at high risk of bleeding owing to acquired PLT dysfunction, such as during extracorporeal membrane oxygenation, commonly receive transfusions to keep their PLT counts $>100 \times 10^9/L$.

Table 471-1 lists guidelines that are acceptable to many neonatologists. One particularly contentious issue is how to manage critically ill neonates receiving drugs/agents known to adversely affect PLT function (e.g., indomethacin, nitric oxide, antibiotics). Some reports suggest increased risk of bleeding for these neonates, but the efficacy of PLT transfusions has not been convincingly proven, particularly when given prophylactically. For optimal PLT transfusion practices, each hospital should modify the guidelines to comply with local practices, and audits/reviews should be performed to avoid violations of the recommended practices. The posttransfusion goal of most PLT transfusions is to raise the PLT count well above $50 \times 10^9/L$, hopefully to $\geq 100 \times 10^9/L$. These increases can be achieved consistently in children weighing up to 30 kg by infusion of 5-10 mL/kg of standard (unmodified) PLT concentrates, obtained either from processing whole blood units or by plateletpheresis. For larger children, the appropriate dose is 3-4 pooled whole blood–derived PLT units or 1 apheresis unit. Because PLT concentration/quantity varies in different PLT products made available for transfusion, each hospital should monitor posttransfusion PLT counts to determine the dose that works best locally. PLT concentrates should be transfused as rapidly as the patient's overall condition permits, certainly within 2 hr. Neonates/infants requiring repeated PLT transfusions should receive leukocyte-reduced blood products, including PLT concentrates, to diminish alloimmunization and PLT refractoriness and to reduce the risk of transfusion-transmitted cytomegalovirus infection.

Routinely reducing the volume of PLT concentrates for infants and small children by additional centrifugation steps is both unnecessary and unwise. Transfusion of 10 mL/kg of an unmodified PLT concentrate is adequate because it adds approximately 10×10^9 PLTs to 70 mL of blood (the estimated intravascular blood volume of a 1 kg neonate), a dose/volume calculated to increase the PLT count by $100 \times 10^9/L$. This calculated increment is consistent with actual posttransfusion increment reported in patients. Moreover, 10 mL/kg is not an excessive transfusion volume, provided that the intake of other IV fluids, medications, and nutrients is monitored and adjusted.

It is important to select PLT units for transfusion with the donor ABO group identical to that of the neonate/infant and to avoid repeated transfusion of group O PLTs to group A or B recipients because passive transfusion anti-A or anti-B in group O plasma, can occasionally lead to hemolysis.

Chapter **472**

Neutrophil (Granulocyte) Transfusions

Ronald G. Strauss

Table 472-1 lists guidelines for granulocyte transfusion (GTX). GTX has been used sparingly in older infants and children. The current ability to collect markedly higher numbers of neutrophils from donors stimulated with combined recombinant granulocyte colony-stimulating factor (G-CSF) plus dexamethasone has led to renewed interest for patients with neutropenic infections, particularly when severe neutropenia is prolonged (e.g., in the setting of placental/cord blood hematopoietic progenitor cell transplantation). Because of the higher neutrophil yields with this collection approach, adding GTX to antibiotics should be considered at institutions where neutropenic patients continue either to die of progressive bacterial and fungal infections or to suffer substantial morbidity despite optimal antiinfection measures, including antibiotics and recombinant myeloid growth factors.

The use of GTX added to antibiotics for children with severe neutropenia (blood neutrophil count $<0.5 \times 10^9$/L) because of bone marrow failure is similar to that for adults. Unfortunately, two randomized clinical trials comparing antibiotics plus GTX from donors stimulated with G-CSF plus dexamethasone versus antibiotics without GTX

Table 472-1	Guidelines for Pediatric Granulocyte Transfusions*
CHILDREN AND ADOLESCENTS	
1. Severe neutropenia (blood neutrophil count $<0.5 \times 10^9$/L) and infection (bacterial, yeast, or fungal) *unresponsive or progressive* despite appropriate antimicrobial therapy	
2. Qualitative neutrophil defect, neutropenia not required, and infection (bacterial or fungal) *unresponsive or progressive* to appropriate antimicrobial therapy	
INFANTS ≤4 MO OLD†	
Blood neutrophil count $<3.0 \times 10^9$/L in 1st wk of life or $<1.0 \times 10^9$/L thereafter and *fulminant* bacterial infection.

†No longer commonly used.

to treat neutropenic infections in children have not provided definitive guidelines. However in practice, neutropenic patients with bacterial infections usually show response to antibiotics alone, provided bone marrow function recovers within the 1st 7-10 days of infection onset so that severe neutropenia is relatively brief. Children with newly diagnosed acute lymphoblastic leukemia show rapid response to induction chemotherapy, and they rarely are candidates for GTX. In contrast, infected children with more sustained bone marrow failure and consequent severe neutropenia (e.g., acute myeloblastic leukemia, malignant neoplasms resistant to treatment, severe aplastic anemia, and placental/cord blood hematopoietic progenitor cell transplant recipients) may benefit when GTX is added to antibiotics.

Currently, the efficacy of GTX obtained from G-CSF plus dexamethasone-stimulated donors for bacterial sepsis unresponsive to antibiotics in patients with severe neutropenia (blood neutrophil count $<0.5 \times 10^9/L$) is not well supported by trials in children. In contrast, GTX efficacy for yeast and fungal infections remains unproven despite transfusing GTX with relatively large numbers of neutrophils.

Children with qualitative neutrophil defects (**neutrophil dysfunction**) usually have adequate or even increased numbers of blood neutrophils but suffer serious infections, because their neutrophils kill pathogenic microorganisms inefficiently. Neutrophil dysfunction syndromes are rare; accordingly, no definitive studies have established GTX efficacy. However, several patients with progressive life-threatening infections have shown striking improvement with the addition of GTX, often given for long periods of time, to antimicrobial therapy. These disorders are chronic, and because of the risk of inducing alloimmunization to leukocyte antigens, and in some patients with chronic granulomatous disease, to antigens of the Kell system of red blood cells, GTX is recommended only when serious infections are clearly unresponsive to antimicrobial drugs.

Neonates are unusually susceptible to severe bacterial infections, and a number of defects of neonatal body defenses contribute, including actual or "relative" neutropenia. Neonates with fulminant sepsis who exhibit relative neutropenia (blood neutrophil count $<3.0 \times 10^9/L$ during the 1st wk of life and $<1.0 \times 10^9/L$ thereafter) and a severely diminished neutrophil marrow storage pool (with <10% of nucleated marrow cells being postmitotic neutrophils) are at risk of dying if treated only with antibiotics. GTX is rarely used because results of clinical trials are mixed and not uniformly convincing, and it is difficult to obtain neutrophil apheresis concentrates in timely fashion.

Current data are insufficient to determine whether recombinant myeloid growth factors have a role in treating septic neonates, despite the fact that both G-CSF and granulocyte-macrophage colony-stimulating factor have been demonstrated to enhance myelopoiesis and raise neutrophil counts in infants. Importantly, G-CSF is efficacious for the long-term treatment of several types of severe congenital neutropenia.

If the decision to provide a GTX has been made, an adequate dose of neutrophils/granulocytes collected by leukapheresis must be transfused as shortly after collection as possible. To facilitate this, experienced donors with required infectious disease (HIV, hepatitis) tests having been done recently (usually within the past 30 days) are selected, and the collected neutrophils are transfused before results of current infectious disease tests are known (i.e., infectious disease test results are "waived").

Neonates and infants weighing <10 kg should receive $1\text{-}2 \times 10^9/kg$ neutrophils per each GTX. Larger infants and small children should receive a minimal total dose of 1×10^{10} neutrophils per each GTX. The preferred dose for adolescents is $5\text{-}8 \times 10^{10}$ neutrophils per each GTX, a dose requiring donors to be stimulated with G-CSF plus dexamethasone. GTX should be given daily until either the infection resolves or the blood neutrophil count is sustained above $1.5 \times 10^9/L$ for a few days. Because neutrophils transfused per the GTX often passively increase the blood neutrophil count, it may be necessary to skip 1-2 days of GTXs to be certain severe neutropenia does not recur, as would be seen if endogenous myelopoiesis had not recovered.

Chapter 473

Plasma Transfusions

Ronald G. Strauss

Guidelines for plasma transfusion in pediatric patients (Table 473-1) are similar to those for adults but with the understanding that plasma levels of coagulant and anticoagulant proteins can be developmentally quite low in preterm infants so that transfusions of plasma and plasma-derived commercial concentrates should be determined by actual bleeding or a significant risk of bleeding, not simply prolonged clotting time results. Plasma is transfused to replace clinically significant deficiencies of plasma proteins for which more highly purified protein concentrates that have been treated to reduce infectious disease risks are not available nearly always to provide clotting proteins when bleeding is occurring or in settings when prevention of bleeding is deemed critical.

Two interchangeable plasma products are available for transfusion, plasma frozen within 8 hr of collection (**fresh-frozen plasma**) and plasma frozen within 24 hr of collection. Although levels of factors V and VIII are modestly reduced in the latter plasma product (generally, not more than 25% lower), they are equally efficacious for all indications for which plasma is transfused (see Table 473-1). Recommendations for the volume of plasma to be transfused vary with the specific protein being replaced and the severity of the deficiency, but a starting dose of 15 mL/kg is usually sufficient to elevate plasma levels satisfactorily.

Transfusion of plasma is efficacious for the treatment of deficiencies of clotting factors II, V, X, and XI. Deficiencies of factor XIII and fibrinogen are treated either with cryoprecipitate or specific commercial concentrates; although for patients being given large doses of plasma (e.g., in massive transfusion settings or to treat bleeding in liver failure), additional sources of fibrinogen may not be necessary, as plasma contains large amounts of fibrinogen. It is always useful to include a measurement of plasma fibrinogen when performing clotting assays (e.g., prothrombin time [PT]/international normalized ratio [INR] and activated partial thromboplastin time [aPTT]). *Transfusion of plasma is not recommended for the treatment of patients with severe hemophilia A or B, von Willebrand disease, or factor VII deficiency, because safer factors VII, VIII, IX, and von Willebrand factor concentrates are available.* Moreover, mild to moderate hemophilia A and certain types of von Willebrand disease can be treated with intranasal or intravenous desmopressin (see Chapter 477). An important use of plasma is for rapid reversal of the effects of warfarin in patients who are actively bleeding or who require emergency surgery (in whom

Table 473-1	Guidelines for Pediatric Plasma Transfusions*
1. *Severe* clotting factor deficiency AND bleeding	
2. *Severe* clotting factor deficiency AND an invasive procedure	
3. *Emergency reversal* of warfarin effects	
4. Dilutional coagulopathy and bleeding (e.g., massive transfusion)	
5. Anticoagulant protein (antithrombin III, proteins C and S) replacement	
6. Plasma exchange replacement fluid for thrombotic thrombocytopenic purpura or for disorders with overt bleeding or in which there is risk of bleeding because of clotting protein abnormalities (e.g., liver failure)	

*Words in *italics* must be defined for local transfusion guidelines.

functional deficiencies of factors II, VII, IX, and X cannot be rapidly reversed by vitamin K). Prothrombin "complex" concentrates can also be used for this purpose.

Results of screening coagulation tests (PT/INR, aPTT, and thrombin times, and plasma fibrinogen levels) should not be assumed by themselves to reflect the integrity of the coagulation system or be regarded as indications for plasma transfusions. This is particularly true for neonates. To justify plasma transfusions, coagulation test results must be related to the patient's clinical condition pertaining to bleeding and/or the risk of bleeding. Transfusion of plasma in patients with chronic liver disease and prolonged clotting times is not recommended unless bleeding is present or an invasive procedure is planned, because correction of the clotting factor deficiencies is brief and of questionable benefit.

Plasma also contains several anticoagulant proteins (antithrombin III, protein C, and protein S) whose deficiencies have been associated with **thrombosis**. In selected situations, plasma may be appropriate as replacement therapy, along with anticoagulant treatment, in patients with these disorders; when available, purified concentrates are preferred. Other indications for plasma include replacement fluid during plasma exchange in patients with thrombotic thrombocytopenic purpura (i.e., thrombotic microangiopathies) or other disorders for which plasma is likely to be beneficial (plasma exchange in a patient with overt bleeding due to the underlying disorder such as Goodpasture syndrome or vasculitis or disorders with significant severe coagulopathy that would be made substantially more severe by replacement using albumin solutions only). Plasma is not indicated for correction of hypovolemia or as immunoglobulin replacement therapy, because safer alternatives exist (albumin or crystalloid solutions and IV immunoglobulin, respectively).

In neonates, clotting times are "physiologically" prolonged owing to developmental deficiency of clotting proteins; plasma should be transfused only after reference to normal values adjusted for the birthweight and age of the infant (i.e., not to normal ranges for older children and adults). The indications for plasma in neonates include: (1) reconstitution of red blood cell (RBC) concentrates to simulate whole blood for use in massive transfusions (exchange transfusion, cardiac bypass surgery, and extracorporeal membrane oxygenation); (2) hemorrhage secondary to vitamin K deficiency; (3) disseminated intravascular coagulation *with* bleeding; and (4) bleeding in congenital coagulation factor deficiency when more specific treatment is either unavailable or inappropriate. The use of prophylactic plasma transfusion to prevent intraventricular hemorrhage in premature infants is not recommended. Plasma should not be used as a suspending agent to adjust the hematocrit values of RBC concentrates before small-volume RBC transfusions to neonates because it offers no apparent medical benefit over the use of sterile solutions such as crystalloid and albumin. Similarly, the use of plasma in partial exchange transfusion for the treatment of neonatal hyperviscosity syndrome is unnecessary, because safer crystalloid or colloid solutions are available.

In the treatment of bleeding infants, cryoprecipitate is often considered because of its small infusion volume. However, cryoprecipitate contains significant quantities of only fibrinogen, von Willebrand factor, and factors VIII and XIII. Thus, it is not effective for treating the usual clinical situation in bleeding infants in which multiple clotting factor deficiencies exist.

In preliminary studies, infusions of very small volumes of recombinant activated factor VII have been lifesaving in patients with hemorrhage caused by several mechanisms. Because the efficacy and toxicity of factor VIIa have not been fully defined in these "off-label" uses (not approved by the U.S. Food and Drug Administration), it must be considered experimental therapy at this time.

Chapter 474

Risks of Blood Transfusions

Ronald G. Strauss

The greatest risk of a blood transfusion is receiving a transfusion intended for another patient; misidentification usually as a result of mistakes made labeling the patient's blood sample sent to the blood bank or not accurately matching the unit with the patient at the time the blood is transfused. This risk is particularly high for infants because identification bands may not be attached directly to their bodies, difficulties in drawing blood samples for pretransfusion compatibility testing may lead to deviations from usual policies, and infants cannot speak to identify themselves. Thus, particular care must be taken to ensure accurate patient and blood sample identification.

Although the infectious disease risks of allogeneic blood transfusions are extremely low, transfusions must be given judiciously because "emerging infections" are a constant threat, and testing is not done for every microorganism possibly transmitted by blood transfusions (Table 474-1, Fig. 474-1). Taking nucleic acid amplification testing

Table 474-1 Estimated Risks in Transfusion Per Unit Transfused in the United States

ADVERSE EFFECT	ESTIMATED RISK
Febrile reaction	1/300
Urticaria or other cutaneous reaction	1/50-100
Red blood cell alloimmunization	1/100
Mistranfusion	1/14,000-19,000
Hemolytic reaction	1/6,000
Fatal hemolysis	1/1,000,000
Transfusion-related acute lung injury (TRALI)	1/5,000
HIV1 and HIV2	1/2,000,000-3,000,000
Hepatitis B	1/100,000-200,000
Hepatitis C	1/1,000,000-2,000,000
Human T-cell lymphotrophic virus (HTLV) I and II	1/641,000
Bacterial contamination (usually platelets)	1/5,000,000
Malaria	1/4,000,000
Anaphylaxis	1/20,000-50,000
Graft-versus-host disease	Uncommon
Immunomodulation	Unknown
Hepatitis A	Unknown
Parvovirus	Unknown
Dengue fever	Unknown
Babesiosis	Unknown
West Nile virus	Unknown

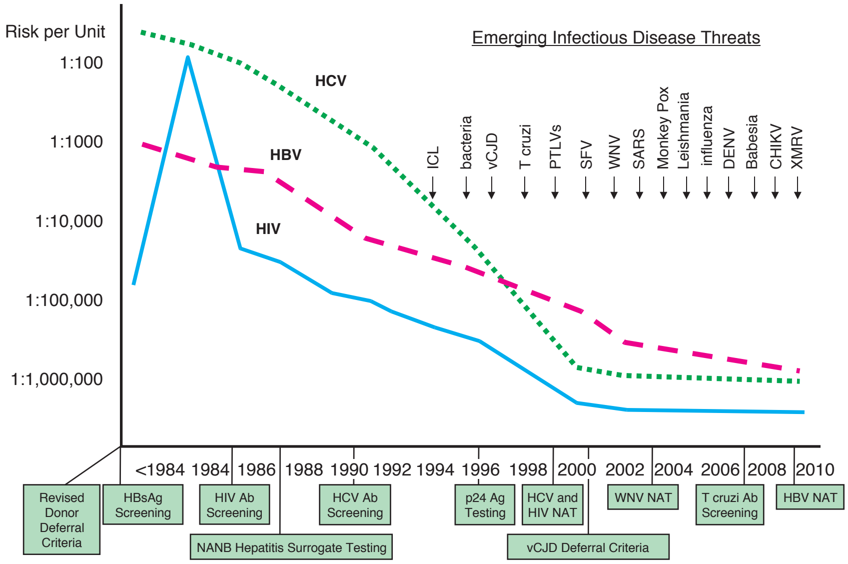

Figure 474-1 **Risks of major transfusion-transmitted viruses related to interventions, and accelerating rate of emerging infectious diseases of concern to blood safety.** Evolution of the risks of transmission by blood transfusion for HIV, hepatitis B virus, and hepatitis C virus. Major interventions to reduce risks are shown below the time line on the x axis. Emerging infectious disease threats in the past 20 yr are shown above in the top right quadrant of the figure. Ab, antibody; Ag, antigen; CHIKV, chikungunya virus; DENV, dengue virus; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; ICL, idiopathic CD4 T-lymphocytopenia; NANB, non-A, non-B hepatitis; NAT, nucleic acid testing; PTLVs, primate T lymphotropic viruses; SARS, severe acute respiratory syndrome; SFV, simian foamy virus; vCJD, variant Creutzfeldt-Jakob disease; WNV, West Nile virus; XMRV, xenotropic murine leukemia virus-related virus. *(From Busch MP. Transfusion-transmitted viral infections: building bridges to transfusion medicine to reduce risks and understand epidemiology and pathogenesis. 2005 Emily Cooley Award Lecture,* Transfusion *46:1624-1640, 2006.)*

(NAT) and all other donor-screening activities (antibody and epidemiology screening) into account, a current estimate of the risk of transfusion-associated HIV is approximately 1 per every 2,000,000 donor exposures. Similarly, with NAT, the risk of viral hepatitis C is 1 per every 1,500,000-2,000,000 donor exposures (Table 474-1). NAT identifies circulating viral nucleic acids that appear in the window period before antibodies develop, and NAT is used routinely to detect HIV, hepatitis C, and West Nile virus. NAT is also available for hepatitis B, but its use for this purpose is variable and controversial.

Transfusion-associated cytomegalovirus (CMV) has been nearly eliminated by transfusion of leukocyte-reduced cellular blood products or by selection of blood collected from donors who are seronegative for antibody to CMV. Although it is logical to hypothesize that first collecting blood components from CMV-seronegative donors and then removing the white blood cells might further improve safety, no data are available to document the superior efficacy of this combined approach. Importantly, considerable care must be taken not to place children at risk of delayed or missed transfusions while awaiting/searching for blood from CMV-seronegative donors to, then, leukocyte-reduce (i.e., risks must not be taken for practices with no established benefits).

Another consideration is that emerging data suggest that this combined approach using CMV-seronegative blood, surprisingly, may be incorrect. Large quantities of CMV viral material are present “free” in the plasma of healthy-appearing donors during the early phase of primary infection (while CMV antibodies are either absent [“window” phase] or are newly emerging and are at low inconsistently detected levels in plasma), rather than being leukocyte-associated as occurs with CMV as substantial quantities of immunoglobulin G antibodies appear. As a result of this biology of CMV primary infection, plasma “free” virus will not be removed by leukocyte-reduction during early infection, and CMV-seronegative donors who may be asymptomatic or deny symptoms of infection during blood donor screening will be misclassified as being CMV safe. They are not safe because antibody is below the limits of detection, while plasma “free” CMV is plentiful during early infection. Because nearly all plasma “free” CMV disappears and becomes almost exclusively cell-associated, once donors are CMV-seropositive with antibody present for several months, it has been proposed that the best method to reduce CMV risk may be to effectively perform leukocyte reduction of blood from donors known to be CMV-seropositive for at least 1 year. However, data to prove the efficacy of this proposal are lacking, and in practice, several studies have shown that the most efficacious method currently available to prevent transfusion-transmitted CMV is to perform leukocyte-reduction in the blood center/bank without regard for the CMV-antibody status of the donor/unit (i.e., leukocyte-reduction alone performed by the blood center/bank is sufficient).

Additional infectious risks include other types of hepatitis (A, B, E) and retroviruses (human T-cell lymphotropic virus types I and II, and HIV-2), syphilis, parvovirus B19, Epstein-Barr virus, human herpesvirus 8, West Nile virus, yellow fever vaccine virus, malaria, babesiosis, *Anaplasma phagocytophilum*, and Chagas disease. Variant Creutzfeldt-Jacob disease has also been transmitted by blood transfusions in humans. All are reported very uncommonly, but nonetheless, provide the rationale to transfuse only when true benefits are likely.

Transfusion-associated risks of a noninfectious nature that may occur include hemolytic and nonhemolytic transfusion reactions, fluid overload, graft versus host disease, electrolyte and acid-base imbalances, iron overload if repeated transfusions are needed long term, increased susceptibility to oxidant damage, exposure to plasticizers, hemolysis with T-antigen activation of red blood cells, posttransfusion purpura, transfusion-related acute lung injury, post-transfusion immunosuppression and immunomodulation, and alloimmunization (see Table 474-1). The risk of transfusion-related acute lung injury may be reduced by reducing the use of plasma or platelets from female donors who were possibly sensitized during pregnancy or are negative for human leukocyte antigen (HLA) antibodies.

Immunologic adverse effects, including immunosuppression, immunomodulation, and alloimmunization may be reduced by leukocyte-reduction. Transfusion reactions and alloimmunization to red blood cell and leukocyte antigens seem to be uncommon in infants, perhaps because of developmental immaturity of the immune system or deficient cytokine production. When they do occur, adverse effects are seen primarily in massive transfusion settings, such as exchange

transfusions and trauma or surgery, in which relatively large quantities of blood are needed but are rare with the small-volume transfusions usually given.

Premature infants are known to have immune dysfunction, but their relative risk of posttransfusion graft-versus-host disease is controversial. The postnatal age of the infant, the number of immunocompetent lymphocytes in the transfusion product, the degree of HLA compatibility between donor and recipient, and other poorly described phenomena determine which infants are truly at risk for graft-versus-host disease. Regardless, many centers caring for preterm infants transfuse exclusively irradiated cellular products. Directed donations with blood drawn from blood relatives must always be irradiated because of the risk of engraftment with transfused HLA-homozygous, haploidentical lymphocytes. Cellular blood products given as intrauterine and/or exchange transfusions should be irradiated, as are transfusions for patients with severe congenital immunodeficiency disorders (severe combined immunodeficiency syndrome and DiGeorge syndrome requiring heart surgery) and transfusions for recipients of hematopoietic progenitor cell transplants. Other groups who are potentially at risk but for whom no conclusive data are available include patients given T-cell antibody therapy (antithymocyte globulin or OKT3), those with organ allografts, those receiving immunosuppressive drug regimens, and those infected with HIV.

Current practice uses irradiation from a cesium, cobalt, or linear acceleration source at doses ranging from 2,500-5,000 cGy; a minimum dose of 2,500 cGy is required. All cellular blood components should be irradiated, but frozen "acellular" products, such as plasma and cryoprecipitate, do not require it. Leukocyte reduction cannot be substituted for irradiation to prevent graft versus host disease.

Section 7

Hemorrhagic and Thrombotic Diseases

Chapter 475

Hemostasis

J. Paul Scott and Leslie J. Raffini

Hemostasis is the active process that clots blood in areas of blood vessel injury yet simultaneously limits the clot size only to the areas of injury. Over time, the clot is lysed by the fibrinolytic system, and normal blood flow is restored. If clotting is impaired, hemorrhage occurs. If clotting is excessive, thrombotic complications ensue. The hemostatic response needs to be rapid and regulated such that trauma does not trigger a systemic reaction but must initiate a rapid, localized response. Key to the speed and coordination of response is that when a platelet adheres to a site of vascular injury, the platelet surface provides a reaction surface where clotting factors bind. The active enzyme is brought together with its substrate and a catalytic cofactor on a reaction surface, accelerating reaction rates and providing activated products for reaction with clotting factors further down the coagulation cascade. Active clotting is controlled by negative feedback loops that inhibit the clotting process when the procoagulant process comes in contact with intact endothelium. The main components of the hemostatic process are the **vessel wall, platelets, coagulation proteins, anticoagulant proteins,** and **fibrinolytic system.** Most components of hemostasis are multifunctional; fibrinogen serves as the ligand between platelets during platelet aggregation and also serves as the substrate for thrombin that forms the fibrin clot. Platelets provide the reaction surface on which clotting reactions occur, form the plug at the site of vessel injury, and contract to constrict and limit clot size.

THE PROCESS

The intact vascular endothelium is the primary barrier against hemorrhage. The endothelial cells that line the vessel wall normally inhibit coagulation and provide a smooth surface that permits rapid blood flow.

After vascular injury, vasoconstriction occurs and flowing blood comes in contact with the subendothelial matrix (Fig. 475-1). In flowing blood, when exposed to subendothelial matrix proteins, von Willebrand factor (VWF) changes conformation and provides the glue to which the platelet VWF receptor, the glycoprotein Ib complex, binds, tethering platelets to sites of injury. When the VWF receptor binds its ligand, complex signaling occurs from the outside membrane receptor to intracellular pathways, activating the platelets and triggering secretion of storage granules containing adenosine diphosphate (ADP), serotonin, and stored plasma and platelet membrane proteins. Upon activation, the platelet receptor for fibrinogen, $\alpha IIb\beta_3$, is switched on ("inside out" signaling) to bind fibrinogen and triggers the aggregation and recruitment of other platelets to form the platelet plug. Multiple physiologic agonists can trigger platelet activation and aggregation, including ADP, collagen, thrombin, and arachidonic acid. Aggregation involves the interaction of specific receptors on the platelet surface with plasma hemostatic proteins, primarily fibrinogen.

One of the subendothelial matrix proteins that are exposed after vascular injury is tissue factor. Just as exposed subendothelial matrix proteins bind VWF, exposed tissue factor binds to factor VII and

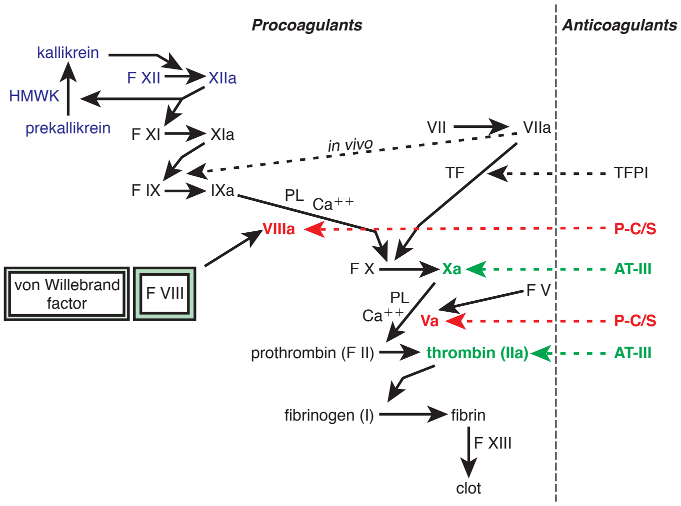

Figure 475-1 The clotting cascade, with sequential activation and amplification of clot formation. Many of the factors (F) are activated by the clotting factors shown above them in the cascade. The activated factors are designated by the addition of an *a*. On the right side, the major anticoagulants and the sites that they regulate are shown: Tissue factor pathway inhibitor (TFPI) regulates tissue factor [TF]); factor VIIa, protein C, and protein S (P-C/S) regulate factors VIII and V; and antithrombin III (AT-III) regulates factor Xa and thrombin (factor IIa). The *dotted line* shows that, in vivo, TF and factor VIIa activate both factors IX and X, but that, in vitro, only the activation of factor X is measured. Unactivated factor VIII, when bound to its carrier protein, von Willebrand factor, is protected from protein C inactivation. When thrombin, or factor Xa activates factor VIII, it becomes unbound from von Willebrand factor, whereupon it can participate with factor IXa in the activation of factor X in the presence of phospholipid (PL) and Ca^{2+} (the "tenase" complex). Factor XIIIa crosslinks the fibrin clot and thereby makes it more stable. Prekallikrein, high-molecular-weight kininogen (HMWK), and factor XII are shown in *blue* because they do not have a physiologic role in coagulation, although they contribute to the clotting time in partial thromboplastin time (PTT).

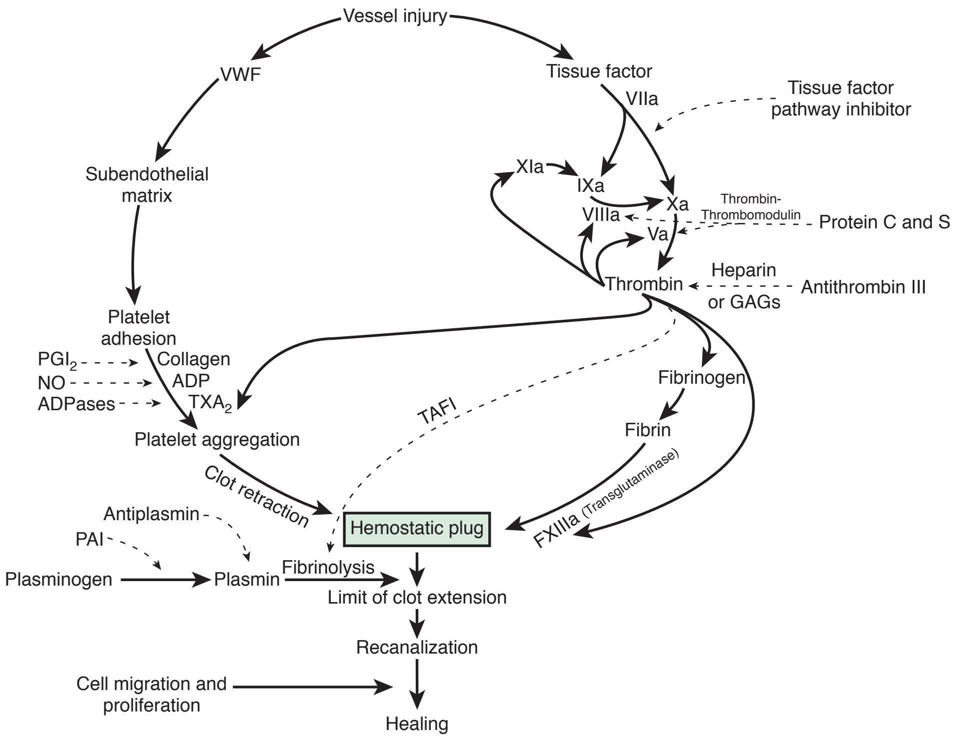

Figure 475-2 The hemostatic mechanism. ADP, adenosine diphosphate; GAGs, glycosaminoglycans; NO, nitric oxide; PGI_2, prostacyclin; PAI, plasminogen activator inhibitor; TAFI, thrombin-activated fibrinolytic inhibitor; TXA_2, thromboxane A_2; VWF, von Willebrand factor.

activates the clotting cascade, as shown in Figure 475-2. The activated clotting factor then initiates the activation of the next sequential clotting factor in a systematic manner. Our understanding of the sequence of steps in the cascade followed assignment of the numerals for the clotting factors for the participant proteins, and thus the sequence seems "out of numerical order." During the process of platelet activation, internalized platelet phospholipids (primarily phosphatidylserine) become externalized and interact at 2 specific, rate-limiting steps in the clotting process—those involving the cofactors factor VIII (X-ase complex) and factor V (prothrombinase complex). Both of these reactions are localized to the platelet surface and bring together the active enzyme, an activated cofactor, and the zymogen that will form the next active enzyme in the cascade. This sequence results in amplification of the process, which supplies a burst of clotting where it is physiologically needed. In vivo, autocatalysis of factor VII generates small amounts of VIIa continuously, so the system is always poised to act. Near the bottom of the cascade, the multipotent enzyme thrombin is formed. Thrombin converts fibrinogen into fibrin, activates factors V, VIII, and XI, and aggregates platelets. Activation of factor XI by thrombin amplifies further thrombin generation and contributes to inhibition of fibrinolysis. Thrombin also activates factor XIII. The stable fibrin-platelet plug is ultimately formed through clot retraction and cross linking of the fibrin clot by factor XIIIa.

Virtually all procoagulant proteins are balanced by an anticoagulant protein that regulates or inhibits procoagulant function. Four clinically important, naturally occurring anticoagulants regulate the extension of the clotting process: antithrombin III (AT-III), protein C, protein S, and tissue factor pathway inhibitor. AT-III is a serine protease inhibitor that regulates factor Xa and thrombin primarily and factors IXa, XIa, and XIIa to a lesser extent. When thrombin in flowing blood encounters intact endothelium, thrombin binds to thrombomodulin, its endothelial receptor. The thrombin–thrombomodulin complex then converts protein C into activated protein C. In the presence of the cofactor protein S, activated protein C proteolyses and inactivates factor Va and factor VIIIa. Inactivated factor Va is, in fact, a functional anticoagulant that inhibits clotting. Tissue factor pathway inhibitor limits activation of factor X by factor VIIa and tissue factor and shifts the activation site of tissue factor and factor VIIa to that of factor IX (see Figs. 475-1 and 475-2).

Once a stable fibrin-platelet plug is formed, the fibrinolytic system limits its extension and also lyses the clot (fibrinolysis) to reestablish vascular integrity. Plasmin, generated from plasminogen by either urokinase-like or tissue-type plasminogen activator, degrades the fibrin clot. In the process of dissolving the fibrin clot, fibrin degradation products are produced. The fibrinolytic pathway is regulated by plasminogen activator inhibitors and α_2-antiplasmin, as well as by the thrombin-activatable fibrinolysis inhibitor. Finally, the flow of blood in and around the clot is crucial, because flowing blood returns to the liver, where activated clotting factor complexes are removed and new procoagulant and anticoagulant proteins are synthesized to maintain homeostasis of the hemostatic system.

PATHOLOGY

Congenital deficiency of an individual procoagulant protein leads to a bleeding disorder, whereas deficiency of an anticoagulant (clotting factor inhibitor) predisposes the patient to thrombosis. In acquired hemostatic disorders, there are frequently multiple problems with homeostasis that perturb and dysregulate hemostasis. A primary illness (sepsis) and its secondary effects (shock and acidosis) activate coagulation and fibrinolysis and impair the host's ability to restore normal hemostatic function. When sepsis triggers **disseminated intravascular coagulation,** platelets, procoagulant clotting factors, and anticoagulant proteins are consumed, leaving the hemostatic system unbalanced and prone to bleeding or clotting. Similarly, newborn infants and patients with severe liver disease have synthetic deficiencies of both procoagulant and anticoagulant proteins. Such dysregulation causes the patient to be predisposed to both hemorrhage and thrombosis with mild or moderate triggers that result in major alterations in the hemostatic process.

In the laboratory evaluation of hemostasis, parameters are manipulated to allow assessment of isolated aspects of hemostasis and limit the multifunctionality of some of its components. The coagulation

process is studied in plasma anticoagulated with citrate to bind calcium, with added phospholipid to mimic the reaction surface normally provided by the platelet membrane and with a stimulus to trigger clotting. Calcium is added to restart the clotting process. This results in anomalies such that the in vivo physiologic pathway of clotting in which factor VIIa activates factor IX is bypassed; instead, in prothrombin time (PT), factor VIIa activates factor X. If this were truly the physiologic situation, then there would be an in vivo bypass mechanism that would ameliorate severe factor VIII and factor IX deficiencies, the 2 most common severe bleeding disorders.

475.1 Clinical and Laboratory Evaluation of Hemostasis

J. Paul Scott, Leslie J. Raffini, and Robert R. Montgomery

HISTORY

For most hemostatic disorders, the clinical history provides the most useful information. To evaluate for a bleeding disorder, the history should determine the site or sites of bleeding, the severity and duration of hemorrhage, and the age at onset. Was the bleeding spontaneous, or did it occur after trauma? Was there a previous personal or family history of similar problems? Did the symptoms correlate with the degree of injury or trauma? Does bruising occur spontaneously? Are there lumps with bruises for which there is minimal trauma? If the patient had previous surgery or significant dental procedures, was there any increased bleeding? If a child or adolescent has had surgery that affects the mucosal surfaces, such as a tonsillectomy or major dental extractions, the absence of bleeding usually rules out a hereditary bleeding disorder. Delayed or slow healing of superficial injuries may suggest a hereditary bleeding disorder. In postpubertal females, it is important to take a careful menstrual history. Because some common bleeding disorders, such as von Willebrand disease (VWD), have a fairly high prevalence, mothers and family members may have the same mild bleeding disorder and may not be cognizant that the child's menstrual history is abnormal. Women with mild VWD who have a moderate history of bruising frequently have a reduction of that bruising during pregnancy or after administration of oral contraceptives. Some medications, such as aspirin and other nonsteroidal antiinflammatory drugs, inhibit platelet function and increase bleeding symptoms in patients with a low platelet count or abnormal hemostasis. Standardized bleeding scores have been developed and are undergoing investigation for their sensitivity and specificity in children.

Outside the neonatal period, thrombotic disorders are relatively rare until adulthood. In the neonate, physiologic deficiencies of procoagulants and anticoagulants cause the hemostatic mechanism to be dysregulated, and clinical events can lead to either hemorrhage or thrombosis. If a child or teenager presents with deep venous thrombosis or pulmonary emboli, a detailed family history must be obtained to evaluate for deep venous thrombosis, pulmonary emboli, myocardial infarction, or stroke in other family members. The presence of thrombosis, especially in the absence of a provoking agent in the child or teenager, should induce the clinician to take a careful family history and consideration of evaluation for a hereditary or acquired predisposition to thrombosis.

PHYSICAL EXAMINATION

The physical examination should focus on whether bleeding symptoms are associated primarily with the mucous membranes or skin (mucocutaneous bleeding) or with the muscles and joints (deep bleeding). The examination should determine the presence of petechiae, ecchymoses, hematomas, hemarthroses, or mucous membrane bleeding. Patients with defects in platelet-blood vessel wall interaction (VWD or platelet function defects) usually have mucocutaneous bleeding, which may include epistaxis, menorrhagia, petechiae, ecchymoses, occasional hematomas, and, less commonly, hematuria and gastrointestinal bleeding. Individuals with a clotting factor deficiency of factor VIII or IX (hemophilia A or B) have symptoms of deep bleeding into muscles and joints, with much more extensive ecchymoses and hematoma formation. Patients with mild VWD or other mild bleeding disorders may have no abnormal findings on physical examination. Individuals with disorders of the collagen matrix and vessel wall may have loose joints and lax skin associated with easy bruising (**Ehlers-Danlos syndrome**).

Patients undergoing evaluation for thrombotic disorders should be asked about swollen, warm, tender extremities or internal organs (venous thrombosis), unexplained dyspnea or persistent "pneumonia," especially in the absence of fever (pulmonary emboli), and varicosities and postphlebitic changes. Arterial thrombi usually cause an acute, dramatic impairment of organ function, such as stroke, myocardial infarction, or a painful, white, cold extremity.

LABORATORY TESTS

In patients who have a positive bleeding history or who are actively hemorrhaging, a platelet count, PT, and partial thromboplastin time (PTT) should be performed as screening tests. In individuals with abnormal screening tests, further evaluation should be based upon those results. In a patient with an abnormal bleeding history and a positive family history, normal screening tests should not preclude further laboratory evaluation, which may include a thrombin time, VWF testing, and platelet function studies.

There are no useful routine screening tests for hereditary thrombotic disorders. If the family history is positive or clinical thrombosis is unexplained, specific thrombophilia assays should be performed. Thrombosis is rare in children, and when it is present, the possibility of a hereditary predisposition should be considered (see Chapter 478).

Platelet Count

Platelet count is essential in the evaluation of the child with a positive bleeding history because thrombocytopenia is the most common acquired cause of a bleeding diathesis in children. Patients with a platelet count of >50,000/mm^3 rarely have significant clinical bleeding. Thrombocytosis in children is usually reactive and is not associated with bleeding or thrombotic complications. Persistent, severe thrombocytosis in the absence of an underlying illness may require evaluation for the very rare pediatric presentation of essential thrombocythemia or polycythemia vera.

Prothrombin Time and Activated Partial Thromboplastin Time

Because clotting factors were named in the order of discovery, they do not necessarily reflect the sequential order of activation (Table 475-1). In fact, factors III, IV, and VI were not subsequently found to be independent proteins; thus, these terms are no longer used. Only 2 factors have commonly used names: fibrinogen (factor I) and prothrombin (factor II). The dual mechanisms of activating clotting have been termed the **intrinsic** (surface activation) and **extrinsic** (tissue factor–mediated) pathways. Study of the hemostatic mechanism is further complicated in that the interactions in vivo may use different pathways from those studied in clinical laboratory testing. PT measures the activation of clotting by tissue factor (thromboplastin) in the presence of calcium. Addition of tissue factor causes a burst of factor VIIa generation. The tissue factor–factor VIIa complex activates factor X. Whether factor X is activated by the intrinsic or the extrinsic pathway, factor Xa on the platelet phospholipid surface complexes with factor V and calcium (the "prothrombinase" complex) to activate prothrombin to thrombin (also referred to as *factor IIa*). Once thrombin is generated, fibrinogen is converted to a fibrin clot, the end point of the reaction (see Fig. 475-2). PT is not prolonged with deficiencies of factors VIII, IX, XI, and XII. In most laboratories, the normal PT value is 10-13 sec. PT has been standardized using the **international normalized ratio (INR)** so that values can be compared from one laboratory or instrument to another. This ratio is used to determine similar degrees of anticoagulation with warfarin (Coumadin)–like medications.

Table 475-1 Coagulation Factors

CLOTTING FACTOR	SYNONYM	DISORDER
I	Fibrinogen	Congenital deficiency (afibrinogenemia) or dysfunction (dysfibrinogenemia)
II	Prothrombin	Congenital deficiency or dysfunction
V	Labile factor, proaccelerin	Congenital deficiency (parahemophilia)
VII	Stable factor or proconvertin	Congenital deficiency
VIII	Antihemophilic factor	Congenital deficiency is hemophilia A (classic hemophilia)
IX	Christmas factor	Congenital deficiency is hemophilia B (sometimes referred to as Christmas disease)
X	Stuart-Prower factor	Congenital deficiency
XI	Plasma thromboplastin antecedent	Congenital deficiency (sometimes referred to as hemophilia C)
XII	Hageman factor	Congenital deficiency is not associated with clinical symptoms
XIII	Fibrin-stabilizing factor	Congenital deficiency

Partial Thromboplastin Time

The intrinsic pathway involves the initial activation of factor XII, which is accelerated by 2 other plasma proteins, prekallikrein and high-molecular-weight kininogen. In the clinical laboratory, factor XII is activated using a surface (silica or glass) or a contact activator, such as ellagic acid. Factor XIIa, in turn, activates factor XI to factor XIa, which then catalyzes factor IX to factor IXa. On the platelet phospholipid surface, factor IXa complexes with factor VIII and calcium to activate factor X ("tenase" complex).

This process is accelerated by interaction with phospholipid and calcium at the steps involving factors V and VIII. An isolated deficiency of a single clotting factor may result in isolated prolongation of PT, PTT, or both, depending on the location of the factor in the clotting cascade. This approach is useful in determining hereditary clotting factor deficiencies; however, in acquired hemostatic disorders encountered in clinical practice, >1 clotting factor is frequently deficient, so the relative prolongation of PT and PTT must be assessed.

Measurement of PTT as performed in the clinical laboratory is actually "activated" PTT; however, most refer to it as *PTT.* This test measures the initiation of clotting at the level of factor XII through sequential steps to the final clot end point. It does not measure factor VII, factor XIII, or anticoagulants. PTT uses a contact activator (silica, kaolin, or ellagic acid) in the presence of calcium and phospholipid. Because of differences in reagents and laboratory instruments, the normal range for PTT varies among hospital laboratories. Normal ranges for PTT are much more variable from laboratory to laboratory than those for PT.

Thus, the mechanisms studied by PT and PTT allow the evaluation of clotting factor deficiencies, even though these pathways may not be the same as those occurring physiologically. In vivo, factor VIIa activates factors IX and X, but as routinely studied in the clinical laboratory, the pathway through which factor VIIa activates factor IX is not evaluated. If the tissue factor–factor VIIa complex activated only factor X, it would be difficult to explain why the most severe bleeding disorders are deficiencies of factor VIII (hemophilia A) and factor IX (hemophilia B). In vivo, thrombin is generated and feeds back to activate factor XI and accelerate the clotting process. Clotting in PTT can be prolonged by deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen, yet these deficiencies are asymptomatic conditions.

Thrombin Time

Thrombin time measures the final step in the clotting cascade, in which fibrinogen is converted to fibrin. The normal thrombin time varies between laboratories but is usually 11-15 sec. Prolongation of thrombin time occurs with reduced fibrinogen levels (*hypofibrinogenemia* or *afibrinogenemia*), with dysfunctional fibrinogen (*dysfibrinogenemia*), or in the presence of substances that interfere with fibrin polymerization, such as heparin and fibrin split products. If heparin contamination is a potential cause of prolonged thrombin time, a reptilase time is usually ordered. Alternatively, heparanase can be added to the sample and the thrombin time repeated.

Reptilase Time

Reptilase time uses snake venom to clot fibrinogen. Unlike thrombin time, reptilase time is not sensitive to heparin and is prolonged only by reduced or dysfunctional fibrinogen and fibrin split products. Therefore, if thrombin time is prolonged but reptilase time is normal, the prolonged thrombin time is due to heparin and does not indicate the presence of fibrin split products or reduced concentration or function of fibrinogen.

Mixing Studies

If there is unexplained prolongation of PT or PTT, a mixing study is usually performed. Normal plasma is added to the patient's plasma, and the PT or PTT is repeated. Correction of PT or PTT by 1 : 1 mixing with normal plasma suggests deficiency of a clotting factor, because a 50% level of individual clotting proteins is sufficient to produce normal PT or PTT. If the clotting time is not corrected or only partially corrected, an inhibitor is usually present. An inhibitor of clotting may be either a chemical similar to heparin that delays coagulation or an antibody directed against a specific clotting factor or the phospholipid used in clotting tests. In the inpatient setting, the most common cause of this finding is heparin contamination of the sample. The presence of heparin in the sample can be ruled in or out either by addition of heparinase to the sample and repeating the thrombin time. If the mixing study is not corrected or if its result becomes more prolonged and the patient has clinical bleeding, an inhibitor of a specific clotting factor (antibody directed against the factor), most commonly factor VIII, factor IX, or factor XI, may be present. If the patient has no bleeding symptoms and both PTT and the mixing study are prolonged, a lupus-like anticoagulant (see Chapter 476) is often present. Patients with these findings usually have a long PTT, do not bleed, and may have a clinical predisposition to excessive clotting.

Bleeding Time

Bleeding time assesses the function of platelets and their interaction with the vascular wall. Disposable standardized devices have been developed that control the length and depth of the skin incision. A blood pressure cuff is applied to the upper arm and inflated to 40 mm Hg for children and adults. In term newborns and younger children, a modified device has been developed that is used with a lower blood pressure cuff pressure. Bleeding time is a difficult laboratory test to standardize, and there is much interlaboratory and interindividual variation. Although platelet counts of <100,000/mm^3 are associated with prolonged bleeding time, disproportionate prolongation of

bleeding time may suggest a qualitative platelet defect or VWD. Use of the bleeding time is declining in many centers.

Platelet Function Analyzer

In an attempt to evaluate the early stages of hemostasis (platelet function and VWF interaction under high shear), several in vitro platelet analyzers have been developed. The greatest experience has been with the platelet function analyzer (PFA-100, Siemens Healthcare Diagnostics, Inc., Deerfield, IL). The PFA-100 measures platelet adhesion-aggregation in whole blood at high shear when exposed to either collagen-epinephrine or collagen-ADP. Results are reported as the closure time measured in sec. The PFA-100 appears to be sensitive to severe forms of VWD and platelet dysfunction. The PFA-100 has variable sensitivity, particularly in the detection of mild VWD and some platelet function defects. Its use as a preoperative screening tool has been disappointing in some studies.

D-Dimer

D-dimer is formed by plasmin degradation of crosslinked fibrin, produced when fibrinogen is clotted by thrombin and cross-linked by factor XIIIa and is more specific for fibrinolysis than fibrin degradation products. D-dimer is elevated in patients with disseminated intravascular coagulation or acute deep vein thrombosis but is relatively nonspecific in that other ill hospitalized patients often have elevated levels of D-dimer. Adult studies show that the D-dimer can be useful to help exclude venous thrombosis and pulmonary embolus because of its high negative predictive value; for example, a patient with a normal D-dimer value is unlikely to have an acute thrombosis.

Clotting Factor Assays

Each of the clotting factors can be measured in the clinical laboratory using individual factor–deficient plasmas. For most clotting factors, activity is measured against pooled normal plasma or against a standard, by which 100% activity is expressed as 100 IU/dL. By definition, 1 IU of each factor is defined as that amount in 1 mL of normal plasma referenced against a standard established by the World Health Organization. For most clotting factors, the normal range is 50-150 IU/dL (50-150%) (Table 475-2).

In patients with hemophilia A or hemophilia B, inhibitors of factor VIII or factor IX may develop after exposure to replacement therapy.

Table 475-2 Reference Values for Coagulation Tests in Healthy Children*

TEST	28-31 Wk GESTATION	30-36 Wk GESTATION	FULL TERM	1-5 Yr	6-10 Yr	11-18 Yr	ADULT

*All factors except fibrinogen are expressed as units/mL (fibrinogen in mg/mL), in which pooled normal plasma contains 1 unit/mL. All data are expressed as the mean, followed by the upper and lower boundaries encompassing 95% of the normal population (shown in parentheses). Normal ranges above vary based on the reagents and instruments used.

†Levels for 19-27 wk and 28-31 wk gestation are from multiple sources and cannot be analyzed statistically.

‡Values are significantly different from those of adults.

§Values are significantly different from those of full-term infants.

ǁValue given as CTA (Committee on Thrombolytic Agents) units/mL. Normal ranges above vary based on the reagents and instruments used.

Data from Andrew M, Paes B, Johnston M: Development of the hemostatic system in the neonate and young infant, Am J Pediatr Hematol Oncol *12:95, 1990; and Andrew M, Vegh P, Johnston M, et al: Maturation of the hemostatic system during childhood,* Blood *80:1998, 1992.*

To quantitate the amount of inhibitor present, the standardized clinical assay of these clotting inhibitors is the Bethesda assay. One Bethesda unit is defined as the amount that will inhibit 50% of the clotting factor in normal plasma.

Platelet Aggregation

When a qualitative platelet function defect is suspected, platelet aggregation testing is usually ordered. Platelet-rich plasma from the patient is activated with 1 of a series of agonists (ADP, epinephrine, collagen, thrombin or thrombin-receptor peptide, and ristocetin). Some platelet aggregometers measure specific adenosine triphosphate release from the platelets, as reflected in generating luminescence (lumiaggregometer), and are more sensitive in detecting abnormalities of the platelet release reaction from storage granules. Repeat testing or testing of other symptomatic family members can help to determine the hereditary nature of the defect. Many medications, especially aspirin, other nonsteroidal antiinflammatory drugs, and valproic acid, alter platelet function testing. Figure 475-1 provides an approach to the differential diagnosis of many common bleeding disorders based on screening tests.

Testing for Thrombotic Predisposition

Hereditary predisposition to thrombosis is associated with a reduction of anticoagulant function (protein C, protein S, AT-III); the presence of a factor V molecule that is resistant to inactivation by protein C (factor V Leiden); elevated levels of procoagulants (a mutation of the prothrombin gene); or a deficiency of fibrinolysis (plasminogen deficiency); and the rare metabolic disease homocystinuria. When patients are being screened for prothrombotic tendencies, specific tests of the natural anticoagulants and polymerase chain reaction analysis for common prothrombotic mutations are warranted. Although both immunologic and functional tests are usually available, functional assays of protein C, protein S, and AT-III are clinically more useful.

Factor V Leiden is a common mutation in factor V that is associated with an increased risk of thrombosis. A point mutation in the factor V molecule prevents the inactivation of factor Va by activated protein C and, thereby, the persistence of factor Va. This defect, also known as *activated protein C resistance,* is easily diagnosed with DNA testing.

The **prothrombin gene mutation (G20210A)** is a mutation in the noncoding portion of the prothrombin gene, with a glycine (G) at position 20210 being replaced by an alanine (A). This mutation increases the amount of prothrombin messenger RNA, is associated with elevations of prothrombin, and causes a predisposition to thrombosis. This abnormality is easily identified with molecular diagnostic (DNA) testing.

Elevated Homocysteine

Levels of homocysteine may be increased as a result of genetic mutations, causing homocystinuria. Patients with homocysteine elevation are predisposed to arterial and venous thrombosis as well as to an increase in arteriosclerosis.

Tests of the Fibrinolytic System

Euglobulin clot lysis time is a screening test used in some laboratories to assess fibrinolysis. More specific tests are available in most laboratories to determine the levels of plasminogen, plasminogen activator, and inhibitors of fibrinolysis. An increase in fibrinolysis may be associated with hemorrhagic symptoms, and a delay in fibrinolysis is associated with thrombosis.

DEVELOPMENTAL HEMOSTASIS

The normal newborn infant has reduced levels of most procoagulants and anticoagulants (see Table 475-1). In general, there is a more marked abnormality in the preterm infant. Although major differences exist in the normal ranges for newborn and preterm infants, these ranges vary greatly among laboratories based upon the instruments and reagents used. During gestation, there is progressive maturation and increase of the clotting factors synthesized by the liver. The extremely premature infant has prolonged PT and PTT values as well as a marked reduction in anticoagulant protein levels (protein C, protein S, and AT-III). Levels of fibrinogen, factors V and VIII, VWF, and platelets are near-normal throughout the later stages of gestation (see Chapter 103.4). Because protein C and protein S are physiologically reduced, the normal factors V and VIII are not balanced with their regulatory proteins. In contrast, the physiologic deficiency of vitamin K–dependent procoagulant proteins (factors II, VII, IX, and X) is partially balanced by the physiologic reduction of AT-III. The net effect is that newborns (especially premature infants) are at increased risk for complications of bleeding, clotting, or both.

Chapter 476

Hereditary Clotting Factor Deficiencies (Bleeding Disorders)

J. Paul Scott and Veronica H. Flood

Hemophilia A (factor VIII deficiency) and **hemophilia B** (factor IX deficiency) are the most common and serious congenital coagulation factor deficiencies. The clinical findings in hemophilia A and hemophilia B are virtually identical. **Hemophilia C** is the bleeding disorder associated with reduced levels of factor XI (see Chapter 476.2). Reduced levels of the *contact factors* (factor XII, high-molecular-weight kininogen, and prekallikrein) are associated with significant prolongation of activated partial thromboplastin time (aPTT; also referred to as *PTT*), but are not associated with hemorrhage, as discussed in Chapter 476.3. Other coagulation factor deficiencies that are less common are briefly discussed in subsequent subchapters.

476.1 Factor VIII or Factor IX Deficiency (Hemophilia A or B)

J. Paul Scott

Deficiencies of factors VIII and IX are the most common severe inherited bleeding disorders. Recombinant factor VIII and factor IX concentrates are available to treat patients with hemophilia and thereby avoid the infectious risk of plasma-derived transfusion-transmitted diseases.

PATHOPHYSIOLOGY

Factors VIII and IX participate in a complex required for the activation of factor X. Together with phospholipid and calcium, they form the “tenase,” or factor X–activating, complex. Figure 475-1 in Chapter 475 shows the clotting process as it occurs in the test tube, with factor X being activated by either the complex of factors VIII and IX or the complex of tissue factor and factor VII. In vivo, the complex of factor VIIa and tissue factor activates factor IX to initiate clotting. In the laboratory, prothrombin time (PT) measures the activation of factor X by factor VII and is therefore normal in patients with factor VIII or factor IX deficiency.

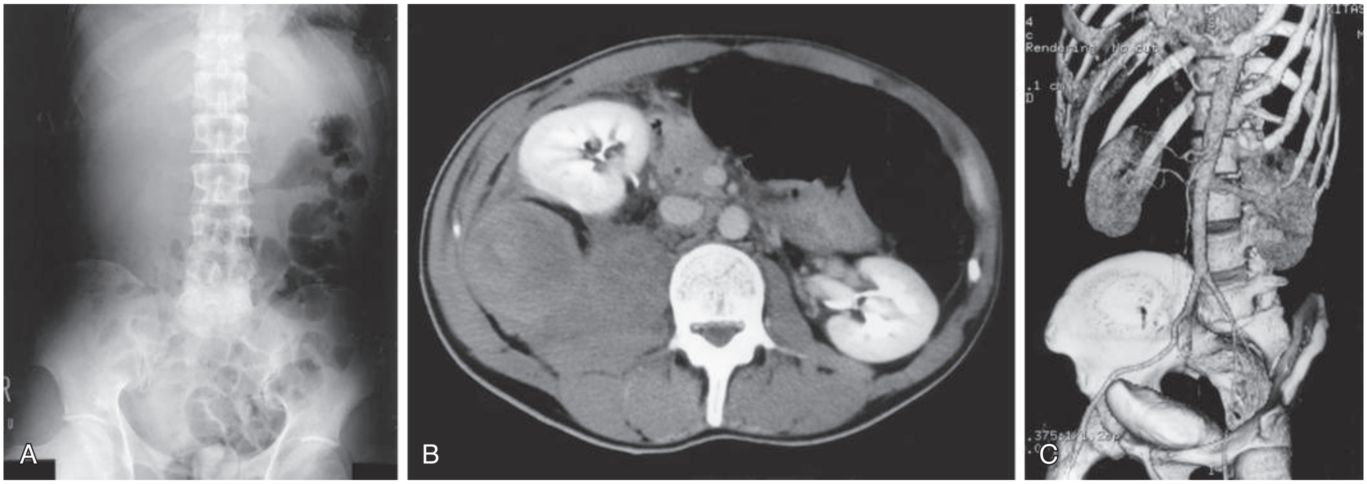

Figure 476-1 Massive hematoma into the iliopsoas muscle in a patient with hemophilia B. A 38 yr old man with severe deficiency of factor IX (hemophilia B) was admitted for right lower abdominal pain of progressively increasing severity and tenderness. He had had a common cold with severe cough and loss of appetite for approximately 1 wk. **A,** Abdominal radiograph shows presence of the psoas sign on the right side and left-shifted colon gas. **B,** CT scan shows massive hematoma in the right iliopsoas muscle, resulting in anterior translocation of the right kidney. **C,** Reconstructed 3-dimensional image shows more clearly the kidney translocation and the extended, but intact, large vessels. These are useful findings for the diagnostic procedures, because progressive right lower abdominal pain may closely simulate acute appendicitis. The hemorrhage was successfully managed by replacement of factor IX for 1 wk without any recurrence. The patient did not have any inhibitors to factor IX. *(From Miyazaki K, Higashihara M: Massive hemorrhage into the iliopsoas muscle,* Intern Med *44:158, 2005.)*

After injury, the initial hemostatic event is formation of the platelet plug, together with the generation of the fibrin clot that prevents further hemorrhage. In hemophilia A or B, clot formation is delayed and is not robust. Inadequate thrombin generation leads to failure to form a tightly crosslinked fibrin clot to support the platelet plug. Patients with hemophilia slowly form a soft, friable clot. When untreated bleeding occurs in a closed space, such as a joint, cessation of bleeding may be the result of tamponade. With open wounds, in which tamponade cannot occur, profuse bleeding may result in significant blood loss. The clot that is formed may be friable, and rebleeding occurs during the physiologic lysis of clots or with minimal new trauma.

CLINICAL MANIFESTATIONS

Neither factor VIII nor factor IX crosses the placenta; bleeding symptoms may be present from birth or may occur in the fetus. Only 2% of neonates with hemophilia sustain intracranial hemorrhages, and 30% of male infants with hemophilia bleed with circumcision. Thus, in the absence of a positive family history (hemophilia has a high rate of spontaneous mutation), hemophilia may go undiagnosed in the newborn. Obvious symptoms such as easy bruising, intramuscular hematomas, and hemarthroses begin when the child begins to cruise. Bleeding from minor traumatic lacerations of the mouth (a torn frenulum) may persist for hours or days and may cause the parents to seek medical evaluation. Even in patients with severe hemophilia, only 90% have evidence of increased bleeding by 1 yr of age. Although bleeding may occur in any area of the body, the hallmark of hemophilic bleeding is **hemarthrosis.** Bleeding into the joints may be induced by minor trauma; many hemarthroses are spontaneous. The earliest joint hemorrhages appear most commonly in the ankle. In the older child and adolescent, hemarthroses of the knees and elbows are also common. Whereas the child's early joint hemorrhages are recognized only after major swelling and fluid accumulation in the joint space, older children are frequently able to recognize bleeding before the physician does. They complain of a warm, tingling sensation in the joint as the first sign of an early joint hemorrhage. Repeated bleeding episodes into the same joint in a patient with severe hemophilia may become a "target" joint. Recurrent bleeding may then become spontaneous because of the underlying pathologic changes in the joint.

Although most muscular hemorrhages are clinically evident owing to localized pain or swelling, bleeding into the iliopsoas muscle requires specific mention. A patient may lose large volumes of blood into the **iliopsoas muscle,** verging on hypovolemic shock, with only a vague area of referred pain in the groin. The hip is held in a flexed, internally rotated position owing to irritation of the iliopsoas. The diagnosis is made clinically from the inability to extend the hip but must be confirmed with ultrasonography or CT (Fig. 476-1). Life-threatening bleeding in the patient with hemophilia is caused by bleeding into vital structures (central nervous system, upper airway) or by exsanguination (external trauma, gastrointestinal or iliopsoas hemorrhage). Prompt treatment with clotting factor concentrate for these life-threatening hemorrhages is imperative. If head trauma is of sufficient concern to suggest radiologic evaluation, factor replacement should precede radiologic evaluation. Simply put: "Treat first, image second!" Life-threatening hemorrhages require replacement therapy to achieve a level equal to that of normal plasma (100 IU/dL, or 100%).

Patients with mild hemophilia who have factor VIII or factor IX levels >5 IU/dL usually do not have spontaneous hemorrhages. These individuals may experience prolonged bleeding after dental work, surgery, or injuries from moderate trauma and may not be diagnosed until they are older.

LABORATORY FINDINGS AND DIAGNOSIS

The laboratory screening test that is affected by a reduced level of factor VIII or factor IX is PTT. In severe hemophilia, the PTT value is usually 2-3 times the upper limit of normal. Results of the other screening tests of the hemostatic mechanism (platelet count, bleeding time, prothrombin time, and thrombin time) are normal. Unless the patient has an inhibitor to factor VIII or IX, the mixing of normal plasma with patient plasma results in correction of PTT value. The specific assay for factors VIII and IX will confirm the diagnosis of hemophilia. If correction does not occur on mixing, an inhibitor may be present. In 25-35% of patients with hemophilia who receive infusions of factor VIII or factor IX, a factor-specific antibody may develop. These antibodies are directed against the active clotting site and are termed *inhibitors.* In such patients, the quantitative Bethesda assay for inhibitors should be performed to measure the antibody titer.

DIFFERENTIAL DIAGNOSIS

In young infants with severe bleeding manifestations, the differential diagnosis includes severe thrombocytopenia; severe platelet function

disorders, such as Bernard-Soulier syndrome and Glanzmann thrombasthenia; type 3 (severe) von Willebrand disease; and vitamin K deficiency. Hemostatic screening tests should differentiate these entities from hemophilia.

GENETICS AND CLASSIFICATION

Hemophilia occurs in approximately 1 : 5,000 males, with 85% having factor VIII deficiency and 10-15% having factor IX deficiency. Hemophilia shows no apparent racial predilection, appearing in all ethnic groups. The severity of hemophilia is classified on the basis of the patient's baseline level of factor VIII or factor IX, because factor levels usually correlate with the severity of bleeding symptoms. By definition, 1 IU of each factor is defined as that amount in 1 mL of normal plasma referenced against a standard established by the World Health Organization (WHO); thus, 100 mL of normal plasma has 100 IU/dL (100% activity) of each factor. For ease of discussion, henceforth in this chapter, we use the term *% activity* to refer to the percentage found in normal plasma (100% activity). Factor concentrates are also referenced against an international WHO standard, so treatment doses are usually referred to in IU. **Severe hemophilia** is characterized as having <1% activity of the specific clotting factor, and bleeding is often spontaneous. Patients with **moderate hemophilia** have factor levels of 1-5% and usually require mild trauma to induce bleeding. Individuals with **mild hemophilia** have levels >5%, may go many years before the condition is diagnosed, and frequently require significant trauma to cause bleeding. The hemostatic level for factor VIII is >30-40%, and for factor IX, it is >25-30%. The lower limit of levels for factors VIII and IX in normal individuals is approximately 50%.

The genes for factors VIII and IX are carried near the terminus of the long arm of the X chromosome and are therefore X-linked traits. The majority of patients with hemophilia have reduced clotting factor protein; 5-10% of those with hemophilia A and 40-50% of those with hemophilia B make a dysfunctional protein. Approximately 45-50% of patients with severe hemophilia A have the same mutation, in which there is an internal inversion within the factor VIII gene that results in production of no protein. This mutation can be detected in the blood of patients or carriers and in the amniotic fluid by molecular techniques. African-Americans often have a different factor VIII haplotype, and this difference may be the reason that African-Americans have higher inhibitor formation (see later). Because of the multiple genetic causes of either factor VIII or factor IX deficiency, most cases of hemophilia are classified according to the amount of factor VIII or factor IX clotting activity. In the newborn, factor VIII values may be artificially elevated because of the acute-phase response elicited by the birth process. This artificial elevation may cause a mildly affected patient to have normal or near-normal levels of factor VIII. Patients with severe hemophilia do not have detectable levels of factor VIII. In contrast, factor IX levels are physiologically low in the newborn. If severe hemophilia is present in the family, an undetectable level of factor IX is diagnostic of severe hemophilia B. In some patients with mild factor IX deficiency, the presence of hemophilia can be confirmed only after several weeks of life.

Through lyonization of the X chromosome, some **female carriers** of hemophilia A or B have sufficient reduction of factor VIII or factor IX to produce mild bleeding disorders. Levels of these factors should be determined in all known or potential carriers to assess the need for treatment in the event of surgery or clinical bleeding.

Because factor VIII is carried in plasma by von Willebrand factor, the ratio of factor VIII to von Willebrand factor is sometimes used to diagnose carriers of hemophilia. When possible, specific genetic mutations should be identified in the propositus and used to test other family members who are at risk of either having hemophilia or being carriers.

TREATMENT

Early, appropriate therapy is the hallmark of excellent hemophilia care. When mild to moderate bleeding occurs, values of factor VIII or factor IX must be raised to hemostatic levels, in the 35-50% range. For life-threatening or major hemorrhages, the dose should aim to achieve levels of 100% activity.

Calculation of the dose of recombinant factor VIII (FVIII) or recombinant factor IX (FIX) is as follows:

$$\text{Dose of rFVIII (IU)} = \%\ \text{desired (rise in rFVIII)} \times \text{Body weight (kg)} \times 0.5$$

$$\text{Dose of rFIX (IU)} = \%\ \text{desired (rise in plasma FIX)} \times \text{Body weight (kg)} \times 1.4$$

For factor VIII, the correction factor is based on the volume of distribution of factor VIII. For factor IX, the correction factor is based on the volume of distribution and the observed rise in plasma level after infusion of recombinant factor IX.

Table 476-1 summarizes the treatment of some common types of hemorrhage in a patient with hemophilia.

With the availability of recombinant replacement products, **prophylaxis is the standard of care** for most children with severe hemophilia, to prevent spontaneous bleeding and early joint deformities. In addition to currently available recombinant factors, products are being developed to increase the plasma half-life and reduce the immunogenicity of hemostatic factors. A study comparing prophylaxis with aggressive episodic treatment provides evidence for the superiority of prophylaxis in preventing debilitating joint disease. If target joints develop, "secondary" prophylaxis is often initiated.

With mild factor VIII hemophilia, the patient's endogenously produced factor VIII can be released by the administration of desmopressin acetate. In patients with moderate or severe factor VIII deficiency, the stored levels of factor VIII in the body are inadequate, and desmopressin treatment is ineffective. The risk of exposing the patient with mild hemophilia to transfusion-transmitted diseases and the cost of recombinant products warrant the use of desmopressin, if it is effective. A concentrated intranasal form of **desmopressin acetate**, not the enuresis or pituitary replacement dose, can also be used to treat patients with mild hemophilia A. The dose is 150 μg (1 puff) for children weighing <50 kg and 300 μg (2 puffs) for children and young adults weighing >50 kg. Most centers administer a trial of desmopressin to determine the level of factor VIII achieved after its infusion. Desmopressin is not effective in the treatment of factor IX–deficient hemophilia.

Preliminary trials of an adeno-associated virus vector containing the factor IX gene are underway with some encouraging initial results.

PROPHYLAXIS

Many patients are now given lifelong prophylaxis to prevent spontaneous joint bleeding. The National Hemophilia Foundation recommends that prophylaxis be considered optimal therapy for children with severe hemophilia. Usually, such programs are initiated with the first joint hemorrhage. Young children often require the insertion of a central catheter to ensure venous access. Such programs are expensive but are highly effective in preventing or greatly limiting the degree of joint pathology; however, complications include central line infection and thrombosis. Treatment is usually provided every 2-3 days to maintain a measurable plasma level of clotting factor (1-2%) when assayed just before the next infusion (trough level). Whether prophylaxis should be continued into adulthood has not yet been adequately studied. If moderate arthropathy develops, prevention of future bleeding will require higher plasma levels of clotting factors. In the older child who is not given primary prophylaxis, secondary prophylaxis is frequently initiated if a target joint develops.

SUPPORTIVE CARE

Although it is easy to tell parents that their child should avoid trauma, this advice is not practical in active children and adolescents. Toddlers are active, are curious about everything, and injure themselves easily. Effective measures include anticipatory guidance, including the use of car seats, seatbelts, and bike helmets, and the importance of avoiding high-risk behaviors. Older boys should be counseled to avoid violent contact sports, but this issue is a challenge. Boys with severe hemophilia often sustain hemorrhages in the absence of known trauma. Early psychosocial intervention helps the family achieve a balance

Table 476-1 Treatment of Hemophilia

TYPE OF HEMORRHAGE	HEMOPHILIA A	HEMOPHILIA B
Hemarthrosis*	50-60 IU/kg factor VIII concentrate† on day 1; then 20-30 IU/kg on days 2, 3, 5 until joint function is normal or back to baseline. Consider additional treatment every other day for 7-10 days. Consider prophylaxis.	80-100 IU/kg on day 1; then 40 IU/kg on days 2, 4. Consider additional treatment every other day for 7-10 days. Consider prophylaxis.
Muscle or significant subcutaneous hematoma	50 IU/kg factor VIII concentrate; 20 IU/kg every-other-day treatment may be needed until resolved	80 IU/kg factor IX concentrate‡; treatment every 2-3 days may be needed until resolved
Mouth, deciduous tooth, or tooth extraction	20 IU/kg factor VIII concentrate; antifibrinolytic therapy; remove loose deciduous tooth	40 IU/kg factor IX concentrate‡; antifibrinolytic therapy§; remove loose deciduous tooth
Epistaxis	Apply pressure for 15-20 min; pack with petrolatum gauze; give antifibrinolytic therapy; 20 IU/kg factor VIII concentrate if this treatment fails‖	Apply pressure for 15-20 min; pack with petrolatum gauze; antifibrinolytic therapy; 30 IU/kg factor IX concentrate‡ if this treatment fails
Major surgery, life-threatening hemorrhage	50-75 IU/kg factor VIII concentrate, then initiate 25 IU/kg q8-12h to maintain trough level >50 IU/dL for 5-7 days, then 50 IU/kg q24h to maintain trough >25 IU/dL for 7 days	120 IU/kg factor IX concentrate‡, then 50-60 IU/kg every 12-24 hr to maintain factor IX at >40 IU/dL for 5-7 days, and then at >30 IU/dL for 7 days
Iliopsoas hemorrhage	50 IU/kg factor VIII concentrate, then 25 IU/kg every 12 hr until asymptomatic, then 20 IU/kg every other day for a total of 10-14 days**	120 IU/kg factor IX concentrate‡; then 50-60 IU/kg every 12-24 hr to maintain factor IX at >40 IU/dL until patient is asymptomatic; then 40-50 IU every other day for a total of 10-14 days**††
Hematuria	Bed rest; 1.5× maintenance fluids; if not controlled in 1-2 days, 20 IU/kg factor VIII concentrate; if not controlled, give prednisone (unless patient is HIV-infected)	Bed rest; 1.5× maintenance fluids; if not controlled in 1-2 days, 40 IU/kg factor IX concentrate‡; if not controlled, give prednisone (unless patient is HIV-infected)
Prophylaxis	20-40 IU/kg factor VIII concentrate every other day to achieve a trough level ≥1%	30-50 IU/kg factor IX concentrate‡ every 2-3 days to achieve a trough level ≥1%

*For hip hemarthrosis, orthopedic evaluation for possible aspiration is advisable to prevent avascular necrosis of the femoral head.
†For mild or moderate hemophilia, desmopressin, 0.3 μg/kg, should be used instead of factor VIII concentrate, if the patient is known to respond with a hemostatic level of factor VIII; if repeated doses are given, monitor factor VIII levels for tachyphylaxis.
‡Stated doses apply for recombinant factor IX concentrate; for plasma-derived factor IX concentrate, use 70% of the stated dose.
§Do not give antifibrinolytic therapy until 4-6 hr after a dose of prothrombin complex concentrate.
‖Nonprescription coagulation-promoting products may be helpful.
**Repeat radiologic assessment should be performed before discontinuation of therapy.
††If repeated doses of factor IX concentrate are required, use highly purified, specific factor IX concentrate.
Adapted from Montgomery RR, Gill JC, Scott JP: Hemophilia and von Willebrand disease. In Nathan DG, Orkin SH, editors: Nathan and Oski's hematology of infancy and childhood, *ed 5, Philadelphia, 1998, WB Saunders.*

between overprotection and permissiveness. Patients with hemophilia should avoid aspirin and other nonsteroidal antiinflammatory drugs that affect platelet function. The child with a bleeding disorder should receive the appropriate vaccinations against hepatitis B, even though recombinant products may avoid exposure to transfusion-transmitted diseases. Patients exposed to plasma-derived products should be screened periodically for hepatitis B and C, HIV, and abnormalities in liver function.

CHRONIC COMPLICATIONS

Long-term complications of hemophilia A and B include chronic arthropathy, the development of an inhibitor to either factor VIII or factor IX, and the risk of transfusion-transmitted infectious diseases. Although an aggressive, or prophylactic, approach to treatment has reduced the problems of chronic arthropathy, these problems have not been eliminated.

Historically, chronic arthropathy has been the major long-term disability associated with hemophilia. The natural history of untreated hemophilia is one of cyclic recurrent hemorrhages into specific joints, including hemorrhages into the same (target) joint. In young children, the joint distends easily and a large volume of blood may fill the joint until tamponade ensues or therapy intervenes. After joint hemorrhage, proteolytic enzymes are released by white blood cells into the joint space, and heme iron induces macrophage proliferation, leading to inflammation of the synovium. The synovium thickens and develops frondlike projections into the joint that are susceptible to being pinched and may induce further hemorrhage. The cartilaginous surface becomes eroded and ultimately may even expose raw bone, leaving the joint susceptible to articular fusion. In the older patient with advanced arthropathy, bleeding into the target joint, with its thickened synovium, causes severe pain, because the joint may have little space to accommodate blood. Once a target joint is seen to be developing, the patient is usually given short- or long-term prophylaxis to prevent progression of the arthropathy and reduce inflammation.

Inhibitor Formation

Infusion of the deficient clotting factor may initiate an immune response in patients with either factor VIII or factor IX deficiency. Inhibitors are antibodies directed against factor VIII or factor IX that block the clotting activity. Failure of a bleeding episode to respond to appropriate replacement therapy is usually the first sign of an inhibitor. Less often, inhibitors are identified during routine follow-up screening for inhibitors. Inhibitors develop in approximately 25-35% of patients with hemophilia A; the percentage is somewhat lower in patients with hemophilia B, many of whom make an inactive dysfunctional protein that renders them less susceptible to an immune response. Highly purified factor IX or recombinant factor IX seems to increase the frequency of inhibitor development, and some anti–factor IX inhibitors induce anaphylaxis. Many patients who have an inhibitor lose it with continued regular infusions. Others have a higher titer of antibody with subsequent infusions and may need to go through **desensitization** (immune tolerance induction) programs, in which high doses of factor VIII for hemophilia A or factor IX for hemophilia B are infused in an attempt to saturate the antibody and permit the body to develop tolerance. Factor IX immune tolerance programs have resulted in nephrotic syndrome in some patients. Rituximab has been used,

off-label (i.e., in a use not approved by the FDA), as an alternate therapy for patients with high inhibitor titers in whom immune tolerance programs have failed. Some centers first begin with prednisone with or without cyclophosphamide; others add cyclosporine if there is a poor response. If desensitization fails, bleeding episodes are treated with either recombinant factor VIIa or activated prothrombin complex concentrates (factor VIII inhibitor bypassing activity). The use of these products bypasses the inhibitor in many instances but may increase the risk of thrombosis. Some patients with low titers of inhibitor can be treated with high-dose factor VIII during a bleeding episode. Patients with inhibitors require referral to a center that cares for many such patients and has a comprehensive hemophilia program.

In the past, plasma-derived treatment products transmitted hepatitis B and C as well as HIV to large numbers of patients with hemophilia. In the era of recombinant products, the risk of acquiring such infections should be minimal, but patients should receive appropriate immunizations against hepatitis B. Those who are exposed to blood products should be monitored for transfusion-related infections. Reports have also identified the transmission of variant Creutzfeldt-Jakob disease to patients receiving therapeutic plasma and may warrant study of patients with hemophilia for prion transmission from plasma-derived factor concentrates.

COMPREHENSIVE CARE

Patients with hemophilia are best managed through comprehensive hemophilia care centers. Such centers are dedicated to patient and family education as well as to the prevention and/or treatment of the complications of hemophilia, including chronic joint disease and inhibitor development as well as infection, such as hepatitis B and C or HIV. Such centers involve a team of physicians, nurses, orthopedists, physical therapists, and psychosocial workers, among others. Education remains crucial in hemophilia care, because patients who are receiving prophylaxis may be less "experienced" in recognizing bleeding episodes than affected children from previous eras.

476.2 Factor XI Deficiency (Hemophilia C)

J. Paul Scott

Factor XI deficiency is an autosomal deficiency associated with mild to moderate bleeding symptoms. It is frequently encountered in Ashkenazi Jews but has been found in many other ethnic groups. In Israel, 1-3/1,000 individuals are homozygous for this deficiency.

The bleeding tendency is not as severe as in factor VIII or factor IX deficiency. The bleeding associated with factor XI deficiency is not correlated with the amount of factor XI. Some patients with severe deficiency may have minimal or no symptoms at the time of major surgery. Because factor XI augments thrombin generation and leads to activation of the fibrinolytic inhibitor thrombin-activatable fibrinolysis inhibitor, surgical bleeding is more prominent in sites of high fibrinolytic activity like the oral cavity. Unless the patient previously had surgery without bleeding, replacement therapy should be considered and given preoperatively, depending on the nature of the surgical procedure. No approved concentrate of factor XI is available in the United States; therefore, the physician must use fresh-frozen plasma (FFP).

Bleeding during minor surgery can be controlled with local pressure. Patients undergoing dental extractions can be monitored closely and may benefit from treatment with fibrinolytic inhibitors like aminocaproic acid, with plasma replacement therapy used only if hemorrhage occurs. In a patient with homozygous deficiency of factor XI, PTT is often longer than it is in patients with either severe factor VIII or factor IX deficiency. The paradox of fewer clinical symptoms in combination with longer PTT is surprising, but it occurs because factor VIIa can activate factor IX in vivo. The deficiency of factor XI can be confirmed by specific factor XI assays. Plasma infusions of 1 IU/kg usually increase the plasma concentration by 2%. Thus, infusion of plasma at 10-15 mL/kg will result in a plasma level of 20-30%, which is usually sufficient to control moderate hemorrhage. Frequent infusions of plasma would be necessary to achieve higher levels of factor XI. Because the half-life of factor XI is usually ≥48 hr, maintaining adequate levels of factor XI commonly is not difficult.

Chronic joint bleeding is rarely a problem in factor XI deficiency, and for most patients, the deficiency is a concern only at the time of major surgery unless there is a second underlying hemostatic defect (e.g., von Willebrand disease).

Bibliography is available at Expert Consult.

476.3 Deficiencies of the Contact Factors (Nonbleeding Disorders)

J. Paul Scott

Deficiency of the "contact factors" (factor XII, prekallikrein, and high-molecular-weight kininogen) causes prolonged PTT but no bleeding symptoms. Because these contact factors function at the step of initiation of the intrinsic clotting system by the reagent used to determine PTT, the PTT is markedly prolonged when these factors are absent. Thus, there is the paradoxical situation in which PTT is extremely prolonged with no evidence of clinical bleeding. It is important that individuals with these findings be well informed about the meaning of their clotting factor deficiency because they do not need treatment, even for major surgery.

476.4 Factor VII Deficiency

J. Paul Scott

Factor VII deficiency is a rare autosomal bleeding disorder that is usually detected only in the homozygous state. Severity of bleeding varies from mild to severe with hemarthroses, spontaneous intracranial hemorrhage, and mucocutaneous bleeding, especially nosebleeds and menorrhagia. Patients with this deficiency have markedly prolonged PT but normal PTT. Factor VII assays show a marked reduction in factor VII. Because the plasma half-life of factor VII is 2-4 hr, therapy with FFP is difficult and is often complicated by fluid overload. A commercial concentrate of recombinant factor VIIa is effective in treating patients with factor VII deficiency.

Bibliography is available at Expert Consult.

476.5 Factor X Deficiency

J. Paul Scott

Factor X deficiency is a rare (estimated 1/1,000,000) autosomal disorder with variable severity. Mild deficiency results in mucocutaneous and posttraumatic bleeding, whereas severe deficiency results in spontaneous hemarthroses and intracranial hemorrhages. Factor X deficiency is the result of either a quantitative deficiency or a dysfunctional molecule. A reduced factor X level is associated with prolongation of both PT and PTT. In patients with hereditary factor X deficiency, factor X levels can be increased with use of either FFP or prothrombin complex concentrate. The half-life of factor X is approximately 30 hr, and its volume of distribution is similar to that of factor IX. Thus, 1 unit/kg will increase the plasma level of factor X by 1%.

Although it is rarely a problem in pediatric patients, **systemic amyloidosis** may be associated with factor X deficiency, owing to the adsorption of factor X on the amyloid protein. In the setting of amyloidosis, transfusion therapy often is not successful because of the rapid clearance of factor X.

476.6 Prothrombin (Factor II) Deficiency

J. Paul Scott

Prothrombin deficiency is caused either by a markedly reduced prothrombin level (hypoprothrombinemia) or by functionally abnormal prothrombin (dysprothrombinemia). Laboratory testing in homozygous patients shows prolonged PT and PTT. Factor II, or prothrombin, assays show a markedly reduced prothrombin level. Mucocutaneous bleeding in infancy and posttraumatic bleeding later are common. Patients are treated with either FFP or, rarely, prothrombin complex concentrates. In prothrombin deficiency, FFP is useful, because the half-life of prothrombin is 3.5 days. Administration of 1 IU/kg of prothrombin will increase the plasma activity by 1%.

Bibliography is available at Expert Consult.

476.7 Factor V Deficiency

J. Paul Scott

Deficiency of factor V is an autosomal recessive, mild to moderate bleeding disorder that has also been termed **parahemophilia.** Hemarthroses occur rarely; mucocutaneous bleeding and hematomas are the most common symptoms. Severe menorrhagia is a frequent symptom in women. Laboratory evaluation shows prolonged PTT and PT. Specific assays for factor V show a reduction in factor V levels. FFP is the only currently available therapeutic product that contains factor V. Factor V is lost rapidly from stored FFP. Patients with severe factor V deficiency are treated with infusions of FFP at 10 mL/kg every 12 hr. Rarely, a patient with a negative family history of bleeding has an acquired antibody to factor V. Often, such a patient does not bleed because the factor V in platelets prevents excessive bleeding.

Bibliography is available at Expert Consult.

476.8 Combined Deficiency of Factors V and VIII

J. Paul Scott

Combined deficiency of factors V and VIII occurs secondary to the absence of an intracellular transport protein that is responsible for transporting factors V and VIII from the endoplasmic reticulum to the Golgi compartments. This explains the paradoxical deficiency of 2 factors, one encoded on chromosome 1 and the other on the X chromosome. Bleeding symptoms are often milder than for hemophilia A and are treated with FFP to replace both factors V and VIII.

476.9 Fibrinogen (Factor I) Deficiency

J. Paul Scott

Congenital afibrinogenemia is a rare autosomal recessive disorder in which there is an absence of fibrinogen. Patients with this disorder do not bleed as frequently as patients with hemophilia and rarely have hemarthroses. Affected patients may present in the neonatal period with gastrointestinal hemorrhage or hematomas after vaginal delivery. In addition to marked prolongation of PT and PTT, thrombin time is prolonged. In the absence of consumptive coagulopathy, an unmeasurable fibrinogen level is diagnostic. In addition to the quantitative deficiency of fibrinogen, a number of dysfunctional fibrinogens have been reported (**dysfibrinogenemia**). Rarely patients with dysfibrinogenemia present with thrombosis. A human fibrinogen concentrate is commercially available for therapy of bleeding episodes in afibrinogenemic patients. Because the plasma half-life of fibrinogen is 2-4 days, treatment with either FFP or cryoprecipitate is also effective. The hemostatic level of fibrinogen is >60 mg/dL. Each bag of cryoprecipitate contains 100-150 mg of fibrinogen. Some clinical assays for fibrinogen are inhibited by high doses of heparin. Thus, a markedly prolonged thrombin time associated with a low fibrinogen level should be evaluated with determination of reptilase time. Prolonged reptilase time confirms that functional levels of fibrinogen are low and that heparin is not present.

476.10 Factor XIII Deficiency (Fibrin-Stabilizing Factor or Transglutaminase Deficiency)

J. Paul Scott

Because factor XIII is responsible for the crosslinking of fibrin to stabilize the fibrin clot, symptoms of delayed hemorrhage are secondary to instability of the clot. Typically, patients have trauma 1 day and then have a bruise or hematoma the next day. Clinical symptoms include mild bruising, delayed separation of the umbilical stump beyond 4 wk in neonates, poor wound healing, and recurrent spontaneous abortions in women. Rare kindreds with XIII deficiency with hemarthroses and intracranial hemorrhage have been described. Results of the usual screening tests for hemostasis are normal in patients with factor XIII deficiency. Screening tests for factor XIII deficiency are based on the observation that there is increased solubility of the clot because of the failure of crosslinking. The normal clot remains insoluble in the presence of 5M urea, whereas in a patient with XIII deficiency, the clot dissolves. More specific assays for factor XIII are immunologic. The half-life of factor XIII is 5-7 days and the hemostatic level is 2-3% activity. There is a heat-treated, lyophilized concentrate of coagulation factor XIII available to treat bleeding episodes or for prophylaxis.

Bibliography is available at Expert Consult.

476.11 Antiplasmin or Plasminogen Activator Inhibitor Deficiency

J. Paul Scott

Deficiency of either antiplasmin or plasminogen activator inhibitor, both of which are antifibrinolytic proteins, results in increased plasmin generation and premature lysis of fibrin clots. Affected patients have a mild bleeding disorder characterized by mucocutaneous bleeding but rarely have joint hemorrhages. Because results of the usual hemostatic tests are normal, further work-up of a patient with a positive bleeding history should include euglobulin clot lysis time (if available), which measures fibrinolytic activity and yields a shortened result in the presence of these deficiencies. Specific assays for α_2-antiplasmin and plasminogen activator inhibitor are available. Bleeding episodes are treated with FFP; bleeding in the oral cavity may respond to aminocaproic acid.

Chapter 477

Von Willebrand Disease

Veronica H. Flood and J. Paul Scott

von Willebrand disease (VWD) is the most common inherited bleeding disorder, with an estimated prevalence cited at 1 : 100 to 1 : 10,000 depending on the criteria used for diagnosis. Patients with VWD typically present with mucosal bleeding. A family history of either VWD or bleeding symptoms and confirmatory laboratory testing are also required for the diagnosis of VWD.

PATHOPHYSIOLOGY

VWD is caused by a defect in von Willebrand factor (VWF). VWF has several functions in coagulation. First, VWF serves to tether platelets to injured subendothelium via binding sites for platelets and for collagen. Second, VWF serves as a carrier protein for factor VIII (FVIII), protecting FVIII from degradation in plasma. VWF is stored in endothelial cells and in platelet Weibel-Palade bodies and circulates as a large multimeric glycoprotein. Shear stress induces a conformational change in VWF that facilitates its ability to bind platelets through a binding site on platelet glycoprotein Ib (GPIb). This enables VWF to recruit platelets to the site of clot formation, a function that is dependent on the high-molecular-weight multimer forms of VWF.

VWD typically presents with mucosal bleeding, similar to that seen with other platelet defects. Epistaxis, easy bruising, and menorrhagia in women are common complaints. Symptoms, however, are variable, and do not necessarily correlate well with VWF levels. Surgical bleeding, particularly with dental extractions or adenotonsillectomy, is another common presentation. Severe type 3 VWD may present with joint bleeds. Most patients will have a family history of bleeding. Women are more likely to be diagnosed with VWD because of the potential for symptoms with menorrhagia, but men and women are equally likely to have VWD. Diagnosis based on symptoms may be difficult, however, as minor bruising and epistaxis are not uncommon in childhood. Significant unexplained bruising is more often from nonaccidental trauma than from an underlying bleeding disorder.

CLASSIFICATION

VWD may be caused by quantitative or qualitative defects in VWF. Mild to moderate quantitative defects are classified as type 1 VWD, while severe quantitative defects, in which there is no detectable VWF protein, are classified as type 3 VWD. The qualitative defects are grouped together as type 2 VWD.

Type 1 VWD is by far the most common type, accounting for 60-80% of all VWD patients. Typical symptoms include mucosal bleeding, such as epistaxis and menorrhagia as well as easy bruising and potentially surgical bleeding. Guidelines from the National Heart, Lung, and Blood Institute of the National Institutes of Health use a VWF level, as measured by the VWF antigen assay (VWF : Ag), of <30 IU/dL for diagnosis of VWD. Patients with VWF : Ag <20-30 IU/dL are most likely to have a genetic defect in VWF. Patients with VWF : Ag between 30 and 50 IU/dL are said to have "low VWF." Whether or not this category truly represents VWD is a subject of some debate. Because some patients with VWF levels in this range do experience bleeding, many physicians elect to treat them, especially for surgeries such as tonsillectomy.

Patients with low VWF may have VWD as a result of increased clearance of their VWF, or type 1C VWD. Diagnosis of this subtype is important because treatment of these patients with desmopressin is likely to be ineffective, necessitating administration of VWF-containing products.

VWF levels can be influenced by external factors. Blood type has long been known to affect VWF, with lower VWF levels seen in people with blood group O. Stress, exercise, and pregnancy all increase VWF levels; therefore, a single normal VWF level does not necessarily rule out the presence of VWD. Certain diseases, such as *hypothyroidism*, and medications, such as *valproic acid*, can lower VWF levels in affected patients. Repeat testing may be required to rule out or confirm a diagnosis of VWD.

Type 3 VWD is the most severe form and presents with symptoms similar to those seen in mild hemophilia. In type 3 VWD, the VWF protein is completely absent. Type 3 VWD is seen at a frequency of approximately 1 in 1,000,000. In addition to mucosal bleeding, patients may experience joint bleeds or central nervous system hemorrhage. Some physicians elect to treat patients with prophylaxis, or modified prophylaxis following injury, given that these patients typically have very low FVIII (<10 IU/dL). Because type 3 VWD is caused by a lack of VWF, treatment with VWF-containing concentrates is required.

Type 2A VWD is characterized by a defect in VWF multimerization and decreased VWF activity in terms of platelet binding. It is the most common of the type 2 variants, accounting for approximately 10% of VWD cases. Type 2A VWD can result from mutations that affect multimer assembly and processing, or mutations that result in increased proteolysis of secreted VWF. Some mutations affect both secretion and clearance of the VWF. Regardless of the mechanism, all type 2A VWD patients lack the high-molecular-weight multimers, and therefore have reduced VWF activity which results in bleeding. Symptoms are typically more severe than those seen in type 1 VWD. Desmopressin may have clinical efficacy for treatment of minor bleeding, but significant surgical challenges or major bleeding symptoms generally require a VWF-containing concentrate for treatment.

Type 2B VWD results from gain-of-function mutations that increase the ability of VWF to bind platelets. This leads to increased clearance of both VWF and platelets from circulation and results in the loss of high-molecular-weight multimers and decreased VWF activity, similar to that seen in type 2A VWD. Special testing is, therefore, required to diagnose type 2B VWD, either by direct measurement of the increased platelet binding or by an increased response to low-dose ristocetin on platelet aggregation testing. Thrombocytopenia is not always present and may be more prominent during times of stress such as surgery or pregnancy. Desmopressin is relatively contraindicated in type 2B VWD as it may accelerate VWF-platelet binding and clearance.

Platelet-type, pseudo-VWD occurs when a mutation in platelet GPIb causes spontaneous binding to VWF and also presents with decreased VWF activity, loss of high-molecular-weight multimers, and thrombocytopenia similar to type 2B VWD. Specific testing is required to distinguish the 2 conditions. Because the defect involves platelets, treatment generally requires platelet transfusion.

Type 2M VWD includes those patients with decreased VWF activity but normal (or near-normal) multimer distribution. This is generally caused by a defect in the ability of VWF to bind platelet GPIb, but this category also includes patients with defects in VWF-collagen interactions. Some minor bleeding in type 2M VWD may respond to desmopressin, but because type 2M VWD is a functional defect, treatment with VWF-containing concentrates is usually required.

Type 2N VWD is characterized by a defect in the ability of VWF to bind FVIII. Some patients with type 2N VWD may be misdiagnosed as mild hemophilia, therefore a high index of suspicion for this diagnosis is required in patients with low FVIII and an absent family history of FVIII deficiency.

LABORATORY DIAGNOSIS

There are no reliable screening tests for VWD. Patients with significant bleeding may present with anemia, and some patients with type 2B VWD or platelet-type, pseudo-VWD may have thrombocytopenia. The partial thromboplastin time may be prolonged if FVIII is low, but especially in mild type 1 VWD it is often normal, precluding use of the partial thromboplastin time as a screening test. Platelet function analysis has been considered as a screening test for VWD, but suboptimal

	Normal	Type 1	Type 1C (Vicenza)	Type 3	Type 2A	Type 2B	Type 2N	Type 2M	PT-VWD

Table 477-1 Laboratory Testing for VWD

TEST	ABBREVIATION	PURPOSE
VWF antigen	VWF:Ag	Measures total amount of VWF protein present
VWF activity	VWF:RCo	Assess interaction of VWF and platelets as mediated by ristocetin
VWF activity/antigen ratio	VWF:RCo/VWF:Ag	A decreased ratio (<0.7) is found in type 2A, type 2B, and type 2M VWD
Factor VIII activity	FVIII	Measures circulating FVIII, which will be very low in type 2N and type 3 VWD
Multimer distribution	VWF multimers	Allows visualization of VWF multimers, used to identify high-molecular-weight multimers, which will be absent in types 2A and 2B VWD

sensitivity and specificity render results difficult to interpret. Bleeding times are similarly unreliable in diagnosis of VWD.

Unfortunately there is no single test that can reliably diagnose VWD. Therefore a panel of tests is usually required. Table 477-1 lists the laboratory tests commonly used in diagnosis of VWD. These include VWF antigen (VWF:Ag), which measures the total amount of VWF protein present, and VWF activity, which is typically performed using the ristocetin cofactor activity assay (VWF:RCo) and provides a measure of the amount of functional VWF. FVIII activity is also usually included in the workup. Another important test is the VWF multimer distribution, although this is not routinely performed by all laboratories. Table 477-2 summarizes the expected laboratory findings for each type of VWD. Figure 477-1 provides more detailed analysis.

Additional specialized testing may be employed to help ascertain the correct diagnosis. Specific testing for type 1C (clearance defects), type 2B, and type 2N VWD can confirm these diagnoses. Genetic diagnosis is not typically performed, partly as a result of the large size of the VWF gene and the large number of benign sequence variations. Large gene deletions are responsible for some cases of VWD and will not be picked up on routine DNA sequencing. Use of genetic diagnosis is increasing, however, particularly for types 2A, 2B, 2M, and 2N VWD.

TREATMENT

Treatment of VWD depends on the type of VWD present and on the reason for treatment. Table 477-3 outlines the options for treatment. In general, type 1 VWD patients may be treated with desmopressin, which increases the amount of circulating VWF by release from storage. The exceptions are the rare type 1 patient who lacks a response to desmopressin, and patients with type 1C VWD who do respond with an increase in VWF levels, but whose rapid clearance of circulating endogenous VWF results in a rapid return to baseline levels. Treatment of types 2 and 3 VWD requires VWF-containing concentrates similar to the treatment of hemophilia. Dosing depends on the type of VWD, and reason for treatment. Careful monitoring of VWF and FVIII levels is recommended to tailor treatment for surgeries and major trauma. For all types of VWD, adjunct therapy should be

Table 477-2 VWD Classification

	TYPE 1	TYPE 3	TYPE 2A	TYPE 2B*	TYPE 2M	TYPE 2N
VWF:Ag	↓	Absent	↓	↓	↓	Normal or ↓
VWF:RCo	↓	Absent	↓↓	↓↓	↓↓	Normal or ↓
FVIII	Normal	↓↓	Normal or ↓	Normal or ↓	Normal or ↓	↓↓

Table 477-3 VWD Treatment

TREATMENT	VWD TYPES	ADMINISTRATION	DOSING
Desmopressin*	Type 1 VWD Some type 2 VWD (use with caution)	IV or IN	0.3 μg/kg IV[†] 1 spray IN (<50 kg) 2 sprays IN (>50 kg)
von Willebrand factor concentrates[‡]	Type 3 VWD Type 2 VWD Severe type 1 VWD (or type 1 clearance defects)	IV	40-60 ristocetin cofactor activity units/kg (adjust dose depending on baseline VWF level and desired peak VWF level)
Antifibrinolytics	Mucosal bleeding, all types of VWD	PO or IV	Aminocaproic acid: 100 mg/kg PO loading dose followed by 50 mg/kg q 6 hours[§] Tranexamic acid: 1300 mg PO tid × 5 days

*Recommended treatment with Stimate brand nasal spray, as this form is concentrated to give 150 μg/spray. Other forms are much more dilute and will not result in desired increase in VWF.
[†]Maximum recommended dose is 20-30 μg/day.
[‡]Currently both Humate-P and Wilate are approved for treatment of VWD. A recombinant VWF preparation is currently undergoing clinical trials.
[§]Maximum recommended dose is 24 g/day.
IN, intranasal; IV, intravenous; PO, oral administration.

considered when possible, such as the use of antifibrinolytics for oral surgery or hormonal treatment for menorrhagia.

Alternate treatment strategies should also be considered, particularly for difficult symptoms or severe VWD. Hormonal therapy for women with menorrhagia, although not specific to VWD, can be very helpful in managing symptoms and improving quality of life. Local treatment of epistaxis, such as nasal cautery or packing, may be helpful in some circumstances. Iron therapy for patients with iron-deficiency anemia may also be required.

Chapter 478

Hereditary Predisposition to Thrombosis

Leslie J. Raffini and J. Paul Scott

Pediatricians are frequently asked to evaluate children for inherited risk factors for thrombosis with symptomatic thrombosis or asymptomatic children who have relatives affected with either thrombosis or thrombophilia. The clinical utility of thrombophilia testing is debated, both in adults and children.

Thrombophilia testing rarely influences the acute management of a child with a thrombotic event. The association between inherited thrombophilia and pediatric thrombosis varies based on the clinical scenario: children with unprovoked thrombotic events have a high prevalence of inherited defects, while the role of thrombophilic defects in children with catheter-related thrombotic events is questionable. Although some thrombophilic defects are associated with a higher risk of recurrent venous thromboembolism in children, how to use these results to guide the duration of therapy has not been determined. Prospective longitudinal analyses of such patients to determine outcome and response to treatment as well as the impact of known thrombophilic states on these outcomes are clearly needed.

The decision to perform thrombophilia testing in an otherwise healthy child with a family history of thrombosis or thrombophilia should be carefully considered, weighing the potential advantages and limitations of such an approach. Given that the absolute risk of thrombosis in children is extremely low (0.07/100,000), it is unlikely that an inherited thrombophilia will have any impact on clinical decision-making for a young child. The risk of thrombosis increases with age, so identification of a thrombophilic defect in an adolescent may guide thromboprophylaxis in high-risk situations (lower extremity casting or prolonged immobility), inform the discussion about estrogen-based contraceptives, and promote lifestyle modification to avoid behavioral prothrombotic risk factors (sedentary lifestyle, dehydration, obesity, and smoking). Limitations of such testing include the cost as well as the potential for causing unnecessary anxiety or false reassurance.

Table 478-1 lists the most common inherited thrombophilias and their prevalence in the general population. The inherited defects in which the pathogenic link is best understood include the factor V Leiden mutation, the prothrombin gene mutation, and deficiencies of

Table 478-1 Common Inherited Thrombophilias and Accompanying Diagnostic Laboratory Studies

THROMBOPHILIA	PREVALENCE IN WHITE POPULATION %	ODDS RATIO FOR FIRST EPISODE VTE IN CHILDHOOD*	LABORATORY STUDIES
Factor V Leiden mutation			DNA-based PCR assay (or screen with activated protein C resistance)
Heterozygote	3-7	3.8	
Homozygote	0.06-0.25	80-100	
Prothrombin 20210 mutation			DNA-based PCR assay
Heterozygote	1-3	2.6	
Homozygote	–	–	
Antithrombin deficiency	0.02-0.04	9.4	Antithrombin activity via chromogenic or clotting assay
Protein S deficiency	0.03-0.13	5.8	Protein S activity via assay or immunologic assay of free and total protein S antigen
Protein C deficiency	0.2	7.7	Protein C activity via chromogenic or clotting assay
Hyperhomocystinemia	–	–	Fasting homocysteine
Elevated VIII	–	–	Factor VIII activity via one-stage clotting or chromogenic assay

*Data from Young G, Albisetti M, Bonduel M, et al: Impact of inherited thrombophilia on venous thromboembolism in children. *Circulation* 118:1373–1382, 2008.
PCR, polymerase chain reaction; VTE, venous thromboembolism.

protein C, protein S, and antithrombin (AT). Elevated levels of factor VIII and homocysteine are associated with thrombosis, though these are less-well characterized and not necessarily genetically determined. Although there are additional alterations in coagulation that have been associated with thrombotic risk, including elevated concentrations of factors IX and XI, heparin cofactor II deficiency, elevated lipoprotein (a), and dysfibrinogenemia, none has gained widespread acceptance in routine testing of children for inherited thrombophilia.

The **factor V Leiden mutation** is the result of a single nucleotide change at nucleotide 1765 within the factor V gene. This mutation causes factor Va to become resistant to inactivation by activated protein C and is the most common inherited risk factor for thrombosis. This defect is also known as *activated protein C resistance*. Approximately 5% of the U.S. white population is heterozygous for this mutation, and it is less prevalent in other ethnic groups. Individuals who are heterozygous have a 5-7–fold increase in risk of venous thrombosis, while homozygotes have a relative risk of 80-100. The baseline annual risk of thrombosis for young women of reproductive age is 1 per 12,500 and increases to 1 per 3,500 for those on oral contraceptives. For young women who are heterozygous for the factor V Leiden mutation and are taking oral contraceptives, this baseline annual risk is increased 20-30–fold (relative risk) to approximately to 1 per 500 women.

The **prothrombin 20210 gene mutation** is a G-to-A transition in the 3′ untranslated region of the gene that results in increased levels of prothrombin messenger RNA. This variant is present in approximately 2% of U.S. whites. It is a weaker risk factor for venous thrombosis than factor V Leiden, with a relative risk of 2-3.

Deficiencies of protein C, protein S, and AT, the natural anticoagulant proteins, are more rare than the common genetic mutations described previously but are associated with a stronger risk of thrombosis. Although heterozygous deficiencies do not often present during childhood, homozygous defects may result in significant symptoms in infancy. Neonates with homozygous deficiencies of AT, protein C, or protein S may present with purpura fulminans. This condition is characterized by rapidly spreading purpuric skin lesions resulting from thromboses of the small dermal vessels followed by bleeding into the skin. In addition, these infants may also develop cerebral thrombosis, ophthalmic thrombosis, disseminated intravascular coagulation, and large vessel thrombosis. An infant with purpuric skin lesions of unknown cause should receive initial replacement with fresh-frozen plasma. Definitive diagnosis can be difficult in the sick premature neonate who may have undetectable levels of these factors but not have a true genetic deficiency. Protein C and AT concentrates are also available and have been demonstrated to be effective.

Both venous and arterial thromboses are common in young patients with **homocystinuria,** an inborn error of metabolism caused by deficiency of cystathione β-synthase. In this very rare condition, plasma levels of homocysteine exceed 100 μmol/L. Much more common are mild to moderate elevations of homocysteine, which may be acquired or associated with a polymorphism in the methylenetetrahydrofolate reductase (*MTHFR*) gene. Although moderate elevations of homocysteine have been associated with both venous and arterial thrombotic events, testing for polymorphisms in the *MTHFR* gene are not indicated, because these polymorphisms are not associated with venous thromboembolism. The pathogenic mechanisms for thrombosis in homocystinemia are not well understood.

Increased plasma concentrations of **factor VIII** (>150 IU/dL) appear to be regulated by both genetic and environmental factors and are associated with an increased risk of thrombosis. Although there is a strong component of heritability contributing to factor VIII levels, the molecular mechanisms responsible for elevated factor VIII are not well understood. Factor VIII is also considered to be an acute-phase reactant, and may increase transiently during periods of inflammation.

Although interpretation of genetic studies (Factor V Leiden and Prothrombin gene mutations) are fairly straightforward, there are several **challenges in interpretation of thrombophilia studies** that are unique to pediatric patients. Neonates have decreased concentrations of protein C, protein S, and AT that increase rapidly over the first 6 mo of life; protein C concentrations remain below adult levels throughout much of childhood. It is important to use pediatric normal ranges when evaluating these values, and recognize that often the normal range overlaps with heterozygous defects and retesting may be required, particularly in young children. There are several nongenetic factors that many also influence the results of inherited thrombophilia testing, including acute thrombosis, infection, inflammation, hepatic dysfunction, nephrotic syndrome, medication and vitamin K deficiency. In some cases, the hereditary nature may be confirmed by testing the parents.

Chapter 479

Thrombotic Disorders in Children

Leslie J. Raffini and J. Paul Scott

Compared to adults, children are generally protected from venous and arterial thromboses. Advancements in the treatment and supportive care of critically ill children, coupled with a heightened awareness of genetic risk factors for thrombosis, have led to an increase in the diagnosis of thromboembolic events (TEs) in children. As a result, TEs are not infrequent in pediatric tertiary care centers and may result in significant acute and chronic morbidity. Despite the fact that TEs in children are increasing in relative terms, they are still rare. This rarity has been the major impediment to prospective clinical trials, resulting in a deficit of evidence-based medicine. Diagnosis and treatment is often extrapolated from adult data.

EPIDEMIOLOGY

Studies have confirmed a significant increase in the diagnosis of venous thromboembolism (VTE) in pediatric tertiary hospitals across the United States. Although the overall incidence of thrombosis in the general pediatric population is quite low (0.07/100,000), the rate of VTE in hospitalized children is 60/10,000 admissions. Infants <1 yr old account for the largest proportion of pediatric VTEs, with a second peak during adolescence.

The majority of children who develop a TE have multiple risk factors that may be acquired, inherited, and/or anatomic (Table 479-1). The presence of a central venous catheter (CVC and peripherally inserted central venous catheter) is the single most important risk factor for VTE in pediatric patients, associated with approximately 90% of neonatal VTE and 60% of childhood VTE. These catheters are often necessary for the care of premature neonates and children with acute and chronic diseases and are used for intravenous hyperalimentation, chemotherapy, dialysis, antibiotics, or supportive therapy. CVCs may damage the endothelial lining and/or cause blood flow disruption, increasing the risk of thrombosis. There are multiple other acquired risk factors that are associated with thrombosis, including trauma, infection, chronic medical illnesses, and medications. Cancer, congenital heart disease, and prematurity are the most common medical conditions associated with TEs.

Antiphospholipid antibody syndrome (APS) is a well-described syndrome in adults characterized by recurrent fetal loss and/or thrombosis. Antiphospholipid antibodies are associated with both venous and arterial thrombosis. The mechanism by which these antibodies cause thrombosis is not well understood. A diagnosis of APS requires the presence of both clinical and laboratory abnormalities (see "Laboratory Testing" below). The laboratory abnormalities must be persistent for 12 wk. Because of the high risk of recurrence, patients with APS often require long-term anticoagulation. It is important to note that healthy children may have a transient lupus anticoagulant, often diagnosed because of a prolonged partial thromboplastin time on routine preoperative testing. These antibodies may be associated with a recent viral infection and are not a risk factor for thrombosis.

Anatomic abnormalities that impede blood flow also predispose patients to thrombosis at an earlier age. Atresia of the inferior vena cava has been described in association with acute and chronic lower extremity deep venous thrombosis (DVT). **May-Thurner syndrome** (compression of the left iliac vein by the overlying right iliac artery) should be considered in patients who present spontaneously with left iliofemoral thrombosis, and **thoracic outlet obstruction** (**Paget-Schroetter syndrome**) frequently presents with effort-related axillary-subclavian vein thrombosis.

Table 479-1	Risk Factors for Thrombosis
General	Indwelling catheter including PICC (peripherally inserted central venous catheter) lines Infection Trauma Surgery Cancer Immobility Cardiac disease/prosthetic valve Systemic lupus Rheumatoid arthritis Inflammatory bowel disease Polycythemia/dehydration Nephrotic syndrome Diabetes Pregnancy Obesity Prematurity Paroxysmal nocturnal hemoglobinuria Antiphospholipid antibody syndrome Thrombotic thrombocytopenic purpura
Inherited thrombophilia	Factor V Leiden mutation Prothrombin mutation Antithrombin deficiency Protein C deficiency Protein S deficiency Homocystinuria Elevated factor VIII Dysfibrinogenemia
Anatomic	Thoracic outlet obstruction (Paget-Schroetter syndrome) May-Thurner syndrome Absence of the inferior vena cava
Medications	Estrogen-containing contraceptives Asparaginase Heparin (heparin-induced thrombocytopenia) Corticosteroids

CLINICAL MANIFESTATIONS

Extremity Deep Vein Thrombosis

Children with acute DVT often present with extremity pain, swelling, and discoloration. A history of a current or recent CVC in that extremity should be very suggestive. Many times, symptoms of CVC-associated thrombosis are more subtle and chronic, including repeated CVC occlusion or sepsis, or prominent venous collaterals on the chest, face, and neck.

Pulmonary Embolism

Symptoms of pulmonary embolism (PE) include shortness of breath, pleuritic chest pain, cough, hemoptysis, fever, and, in the case of massive PE, hypotension and right-heart failure. Based on autopsy studies, PE is often not diagnosed, perhaps because young children are unable to accurately describe their symptoms and their respiratory deterioration may be masked by other conditions (see Chapter 407.1).

Cerebral Sinovenous Thrombosis

Symptoms may be subtle and may develop over many hours or days. Neonates often present with seizures, whereas older children often complain of headache, vomiting, seizures, and focal signs. They may also have papilledema and abducens palsy. Some patients may have a concurrent sinusitis or mastoiditis that has contributed to the thrombosis.

Renal Vein Thrombosis

Renal vein thrombosis is the most common spontaneous TE in neonates. Affected infants may present with hematuria, an abdominal mass, and/or thrombocytopenia. Infants of diabetic mothers are at increased risk, although the mechanism for this increased risk is unknown. Approximately 25% of cases are bilateral.

Peripheral Arterial Thrombosis

With the exception of stroke, the majority of arterial TEs in children are secondary to catheters, often in neonates related to umbilical artery lines or in patients with cardiac defects undergoing cardiac catheterization. Patients with an arterial thrombosis affecting blood flow to an extremity will present with a cold, pale, blue extremity with poor or absent pulses.

Stroke

Ischemic stroke commonly presents with hemiparesis, loss of consciousness, or seizures. This condition may occur secondary to pathology that affects the intracranial arteries (e.g., sickle cell disease, vasculopathy, or traumatic arterial dissection) or may be a result of venous thrombi that embolize to the arterial circulation (placental thrombi, children with congenital heart disease or patent foramen ovale).

Rapidly Progressive Thrombosis/Thrombotic Storm

Rapid progression or multifocal thrombosis is a rare complication of the APS, heparin-induced thrombocytopenia with thrombosis or thrombotic thrombocytopenia purpura while on appropriate antithrombotic therapy. Multiple organ dysfunctions develop in the presence of small vessel occlusion and elevated D-dimer levels. Recurrences may occur as well as postthrombotic syndrome (PTS). Treatment includes aggressive anticoagulation, often with direct thrombin inhibitors or fondaparinux followed by prolonged warfarin therapy.

DIAGNOSIS

Ultrasound with Doppler flow is the most commonly employed imaging study for the diagnosis of upper, or more often lower, extremity VTE. Spiral CT is used most frequently for the diagnosis of PE (Fig. 479-1). Other diagnostic imaging options include CT and MR venography, which are noninvasive, although the sensitivity and specificity of these studies is not known. They may be particularly helpful in evaluating proximal thrombosis. For the diagnosis of cerebral sinovenous thrombosis and acute ischemic stroke, the most sensitive imaging study is brain magnetic resonance imaging with venography or diffusion weighted imaging.

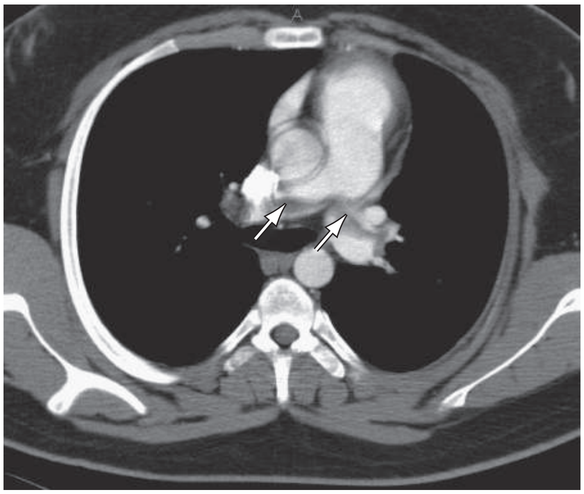

Figure 479-1 Chest CT from a 15 yr old male with a large pulmonary embolism. There are large filling defects in both the right and left main pulmonary arteries.

LABORATORY TESTING

All children with a TE should have a complete blood count and a baseline prothrombin time (PT) and activated partial thromboplastin time (aPTT) to assess their coagulation status. In adults suspected to have a DVT, the D-dimer level has a high negative predictive value. The D-dimer is a fragment produced when fibrin is degraded by plasmin and is a measure of fibrinolysis. Based on the clinical scenario, other laboratory studies, such as renal and hepatic function, may be indicated. Testing for APS includes evaluation for the lupus anticoagulant as well as anticardiolipin and anti–β_2-glycoprotein antibodies.

There is some debate regarding which patients should have testing for inherited risk factors. Thrombophilia testing rarely influences the acute management of a child with a thrombotic event. Identification of an inherited thrombophilia may influence the duration of treatment, particularly for those with combined defects, and may aid in counseling the patient about their risk of recurrence.

The evaluation of coagulation studies in pediatric patients is often complicated the developing hemostatic system and the differences in normal ranges between infants and adults In addition, there is often significant variation in the laboratory assays used to test anticoagulant levels. It is important to refer to the age-related normal ranges when interpreting pediatric coagulation studies. One limitation of these normal ranges is that they were performed many years ago, using assays that may not be equivalent to those used today. Molecular assays are not age dependent.

TREATMENT

Therapeutic options for children with thrombosis include anticoagulation, thrombolysis, surgery, and observation. The goal of **anticoagulation** is to reduce the risk of embolism, halt clot extension, and prevent recurrence. In premature neonates and critically ill children who may have an increased risk of bleeding, the potential benefits must be weighed against the risks. Anticoagulants and thrombolysis are discussed in greater detail in Chapter 479.1. Surgery may be necessary for life- or limb-threatening thrombosis when there is a contraindication to thrombolysis. The optimal treatment for a child with acute ischemic stroke depends on the likely etiology and the size of the infarct. Children with sickle cell disease who develop stroke are treated with chronic red blood cell transfusions to reduce recurrence.

COMPLICATIONS

Complications of VTE include recurrent thrombosis (either local or distant), and development of PTS. A thrombosed blood vessel may partially or fully recanalize or may remain occluded. Over time, an occluded deep vein may cause venous hypertension, resulting in blood flow being directed from the deep system into the superficial veins and potentially producing pain, swelling, edema, discoloration, and ulceration. This clinical picture is known as PTS and may be chronically disabling. Several prospective studies in adults have shown PTS to be present in 17-50% of patients with a history of thrombosis. The likelihood of developing PTS is highest in the first 2 yr but continues to increase over time.

479.1 Anticoagulant and Thrombolytic Therapy

Leslie J. Raffini and J. Paul Scott

Initial options for anticoagulation in children include unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) (Table 479-2). Although there are additional agents, including target specific oral anticoagulants, none have been carefully investigated in children. Both UFH and LMWH act by catalyzing the action of antithrombin (AT)- III. UFH consists of large-molecular-weight polysaccharide chains that interact with AT, catalyzing the inhibition of factor Xa and thrombin, as well as other serine proteases. In contrast, LMWH contains smaller-molecular-weight polysaccharide chains. The interaction of the smaller chains with AT-III results primarily in the inhibition of

Table 479-2 Comparison of Antithrombotic Agents

	rTPA	UNFRACTIONATED HEPARIN*	WARFARIN	LMW HEPARIN (ENOXAPARIN)
Indication	Recent onset of life- or limb-threatening thrombus	Acute or chronic thrombus, prophylaxis	Subacute or chronic thrombosis, thromboprophylaxis for cardiac valves	Acute or chronic thrombus, prophylaxis
Administration	IV, Continuous infusion	IV, Continuous infusion	PO, once daily	SC injection, twice daily
Monitoring	"Lytic state": FDP or D-dimer	PTT	INR	Anti-Xa activity
Other	Higher risk of bleeding	Difficult to titrate, requires frequent dose adjustments	Heavily influenced by drug and diet	More stable and easy to titrate; concern of osteopenia with long-term use

FDP, fibrin degradation product; INR, international normalized ratio; LMW, low-molecular-weight; PTT, partial thromboplastin time; rTPA, recombinant tissue-type plasminogen activator.
*Higher dose is required in newborns.

Xa, with less of an effect on thrombin. There are several LMWHs available, and they have variable inhibitory effects on thrombin. For this reason, the PTT is not a reliable measure of the anticoagulant effect of LMWH, and the anti–factor Xa activity is used instead.

The optimal **duration of anticoagulation** for children with TEs is not well established. Current guidelines recommend that neonates receive 6 wk-3mo of therapy for VTE, and older children receive 3-6 mo of therapy. Patients with strong inherited thrombophilia, recurrent thrombosis, and APS may require indefinite anticoagulation.

UNFRACTIONATED HEPARIN

Heparin Dosing

Based on adult data, a therapeutic heparin dose achieves a prolongation of the aPTT of 1.5-2.5 the upper limit of normal. A bolus dose of 75-100 units/kg results in a therapeutic PTT in the majority of children. This bolus should be followed by a continuous infusion. Initial dosing is based on age, with infants having the highest requirements. It is important to continue to monitor the PTT closely. In some situations, such as patients with a lupus anticoagulant, elevated factor VIII, or neonates, the partial thromboplastin time may not accurately reflect the degree of anticoagulation, and heparin can be monitored using a heparin anti-Xa level of 0.35-0.7 units/mL.

Heparin Complications

Maintaining the aPTT in the therapeutic range can be difficult in young children for several reasons. The bioavailability of heparin is difficult to predict and may be influenced by plasma proteins. In many patients, this results in multiple dose adjustments requiring close monitoring with frequent venipuncture. UFH also requires continuous intravenous access, which may be difficult to maintain in young children.

The most common adverse effect related to heparin therapy is bleeding. This is well documented in the adult medical literature, and there are case reports of serious life-threatening bleeding in children treated with heparin. The true frequency of bleeding in pediatric patients on heparin has not been well established and is reported as 1-24%. If the anticoagulant effect of heparin must be reversed immediately, protamine sulfate may be administered to neutralize the heparin.

Other adverse effects include osteoporosis and heparin-induced thrombocytopenia (HIT). Although rare in pediatric populations, HIT is a prothrombotic, immune-mediated complication in which antibodies develop to a complex of heparin and platelet factor 4. These antibodies result in platelet activation, stimulation of coagulation, thrombocytopenia, and in some cases, life-threatening thrombosis. If HIT is strongly suspected, heparin must be discontinued immediately. There are several alternative parenteral anticoagulants (argatroban, lepirudin, or bivalirudin) that may be used in this situation.

LOW-MOLECULAR-WEIGHT HEPARIN

Because of the ease of dosing and need for less monitoring, **LMWH** is being used more frequently in pediatric patients. Unlike UFH, which is monitored using the aPTT, LMWH is monitored via the anti-Xa activity. The LMWH formulation that has been used most often in pediatric patients is enoxaparin

Enoxaparin Dosing

The recommended standard starting dose of enoxaparin for infants <2 mo is 1.5 mg/kg/dose SQ every 12 hr; for patients >2 mo it is 1 mg/kg SQ every 12 hr. In general, peak levels are achieved 2-6 hr following an injection. A therapeutic anti–factor Xa level, drawn 4 hr after the 2nd or 3rd dose, should be between 0.5 and 1.0 IU/mL. The dose can be titrated to achieve this range. The elimination half-life of enoxaparin is 4-6 hr. Enoxaparin is cleared by the kidney and should be used with caution in patients with renal insufficiency. It should be avoided in patients with renal failure.

After an initial period of anticoagulation with heparin or LMWH, patients may continue to receive LMWH as an outpatient for the duration of therapy, or may be transitioned to an oral anticoagulant, such as warfarin.

WARFARIN

Warfarin is an oral anticoagulant that competitively interferes with vitamin K metabolism, exerting its action by decreasing concentrations of the vitamin K–dependent coagulation factors II, VII, IX, and X, as well as protein C and protein S. Therapy should be started while a patient is anticoagulated with heparin or LMWH because of the risk of warfarin-induced skin necrosis. This transient hypercoagulable condition may occur when levels of protein C drop more rapidly than the procoagulant factors.

Warfarin Dosing

Warfarin therapy is often initiated with a loading dose, with subsequent dose adjustments made according to a nomogram. When initiating a patient on warfarin, UFH or LMWH should be continued until the international normalized ratio (INR) is therapeutic for 2 days. In most cases, this takes 5-7 days. The PT is used to monitor the anticoagulant effect of warfarin. Because the thromboplastin reagents used in PT assays have widely varying sensitivities, it is not possible to compare the PT performed in one laboratory to that performed in another laboratory. As a result, the INR was developed as a mechanism to standardize the variation in the thromboplastin reagent. The target INR range depends on the clinical situation. In general, a range of 2.0-3.0 is the target for the treatment of VTE. High-risk patients, such as those with mechanical heart valves, APS, and recurrent thrombosis, may require a higher target range.

Warfarin Complications

As with the other anticoagulants, bleeding is the most common adverse effect. The risk of serious bleeding in children receiving warfarin for the treatment of VTE has been reported at 1.7%. Children who have supratherapeutic INRs are at higher risk. There is considerable interpatient variation in dose. Diet, medications, and illness may influence the metabolism of warfarin, requiring frequent dose adjustments and laboratory studies. Numerous medications can affect the pharmacokinetics of warfarin by altering its clearance or rate of absorption. This can have a profound effect on the INR, and must be considered when monitoring a patient on warfarin.

The strategies used to reverse warfarin therapy depend on the clinical situation and whether or not there is bleeding. Vitamin K can be administered to reverse the effect of warfarin but takes some time to have effect. If the patient is having significant bleeding, fresh-frozen plasma (15 mL/kg) should be given along with the vitamin K.

Nonhemorrhagic complications are uncommon in children. Warfarin is a teratogen, particularly in the first trimester. Warfarin embryopathy is characterized by bone and cartilage abnormalities known as chondrodysplasia punctata. Affected infants may have nasal hypoplasia and excessive calcifications in the epiphyses and vertebrae.

DIRECT THROMBIN OR FACTOR XA INHIBITORS

Direct thrombin inhibitors (dabigatran) or inhibitors of factor Xa (apixaban, rivaroxaban) have been tested as agents to prevent or treat venous thrombosis in adult populations with increased risk of thrombosis (surgery, immobilization, atrial fibrillation). Fixed dosing, oral administration, no dietary interference with vitamin K, and no need to monitor laboratory tests, as well as initial results suggesting noninferiority to warfarin and fewer bleeding episodes, have favored the use of these agents. Currently there is a paucity of evidence of their utility in children.

THROMBOLYTIC THERAPY

Although anticoagulation alone is often effective at managing thrombosis, there are times when more rapid clot resolution is necessary or desirable. In these situations, thrombolytic agents that activate the fibrinolytic system are of potential benefit. The pharmacologic activity of thrombolytic agents is dependent on the conversion of endogenous plasminogen to plasmin. Plasmin is then able to degrade several plasma proteins including fibrin and fibrinogen. Because of the high risk of bleeding, thrombolytic therapy is generally reserved for patients with life or limb-threatening thrombosis.

Tissue plasminogen activator (TPA) is available as a recombinant product and has become the primary agent used for thrombolysis in children, although proper dose finding studies have not been performed in a pediatric population.

Dosing

There is an extremely wide range of doses of TPA that have been used for systemic therapy, and there is no consensus as to the optimal dose. Previously recommended doses of systemic TPA were 0.1-0.6 mg/kg/hr; however there are recent reports of successful therapy with fewer bleeding complications using prolonged infusions with very low doses—0.01-0.06 mg/kg/hr.

Monitoring

There is no specific laboratory test to document a “therapeutic range” for thrombolytic therapy. It is important to maintain the fibrinogen >100 mg/dL and the platelet count >75,000/mm^3 during treatment. Supplementation of plasminogen using fresh-frozen plasma is generally recommended in neonates prior to initiating thrombolysis because of their low baseline levels.

The clinical and radiologic response to thrombolysis should be closely monitored. The duration of therapy depends on the clinical response. Invasive procedures including urinary catheterization, arterial puncture and rectal temperatures should be avoided.

The role of adjuvant UFH during thrombolytic therapy is controversial. Animal models have demonstrated that thrombolytic therapy can induce a procoagulant state with activation of the coagulation system, generation of thrombin, and extension or reocclusion of the thrombosis. In pediatric patients thought to be at low risk for bleeding, adjuvant UFH should be considered using doses of 10-20 units/kg/hr.

Complications

The most serious complication from thrombolysis is bleeding, which has been reported in 0-40% of patients. Absolute contraindications to thrombolysis include major surgery within 7 days, history of significant bleeding (intracranial, pulmonary or gastrointestinal), peripartum asphyxia with brain damage, uncontrolled hypertension and severe thrombocytopenia. In the event of serious bleeding, thrombolysis should be stopped and cryoprecipitate may be given to replace fibrinogen.

THROMBOPROPHYLAXIS

There have been no formal trials of prevention of venous thromboembolic disease in children. Hospitalized adolescents with multiple risk factors for thrombosis who are immobilized for a protracted time may benefit from prophylactic treatment with enoxaparin 0.5 mg/kg q12hr (maximum: 30 mg).

ANTIPLATELET THERAPY

Inhibition of platelet function using agents such as **aspirin** is more likely to be protective against arterial TEs than VTEs. Aspirin, also known as acetylsalicylic acid, exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase, preventing platelet thromboxane A_2 production. Aspirin is used routinely in children with Kawasaki disease and may also be useful in children with stroke, ventricular assist devices, and those with single-ventricle cardiac defects. The recommended dose of aspirin to achieve an antiplatelet effect in children is 1-5 mg/kg/day.

Chapter 480

Postneonatal Vitamin K Deficiency

J. Paul Scott

Although "late" hemorrhagic disease has been reported in breastfed children, vitamin K deficiency occurring after the neonatal period is usually secondary to a lack of oral intake of vitamin K, alterations in the gut flora as a consequence of the long-term use of broad-spectrum antibiotics, liver disease, or malabsorption of vitamin K. Intestinal malabsorption of fats may accompany cystic fibrosis or biliary atresia and result in a deficiency of fat-soluble dietary vitamins, with reduced synthesis of vitamin K–dependent clotting factors (factors II, VII, IX, and X, and proteins C and S). Prophylactic administration of water-soluble vitamin K orally is indicated in these cases (2-3 mg/24 hr for children and 5-10 mg/24 hr for adolescents and adults), or vitamin K may be administered at 1-2 mg IV. In patients with advanced cirrhosis, synthesis of many of the clotting factors may be reduced because of hepatocellular damage. In these patients, vitamin K may be ineffective. The anticoagulant properties of warfarin (Coumadin) and related anticoagulants depend on interference with vitamin K, with a concomitant reduction of factors II, VII, IX, and X. Rat poison (superwarfarin) produces a similar deficiency; vitamin K is a specific antidote.

Chapter **481**

Liver Disease

J. Paul Scott

Because all of the clotting factors, except factor VIII, are produced exclusively in the liver, coagulation abnormalities are very common in patients with severe liver disease. Only 15% of such patients have significant clinical bleeding states. The severity of the coagulation abnormality appears to be directly proportional to the extent of hepatocellular damage. The most common mechanism causing the defect is decreased synthesis of coagulation factors. Patients with severe liver disease characteristically have normal to increased (not reduced) levels of factor VIII activity in plasma. In some instances, disseminated intravascular coagulation (see Chapter 483) or hyperfibrinolysis may complicate liver disease, making laboratory differentiation of severe liver disease from disseminated intravascular coagulation difficult.

Treatment of the coagulopathy of liver disease should be reserved for patients with clinical bleeding. Because a reduction in vitamin K–dependent coagulation factors is common in those with acute or chronic liver disease, vitamin K therapy can be given as a trial. Vitamin K can be given orally, subcutaneously, or intravenously (not intramuscularly) at a dose of 1 mg/24 hr for infants, 2-3 mg/24 hr for children, and 5-10 mg/24 hr for adolescents and adults. Inability to correct coagulopathy with vitamin K indicates that the coagulopathy may be caused by reduced levels of clotting factors that are not vitamin K–dependent and/or by inadequate production of precursor vitamin K proteins. Treatment for bleeding consists of factor replacement with fresh-frozen plasma (FFP) or cryoprecipitate. FFP (10-15 mL/kg) contains all clotting factors, but replacement of fibrinogen for severe hypofibrinogenemia may require cryoprecipitate at a dose of 1 bag/5 kg body weight. In severe liver disease, it is often difficult to attain correction of abnormal clotting studies despite vigorous therapy with FFP and cryoprecipitate. Some patients with bleeding as a result of liver disease have responded to therapy with desmopressin, and others have responded to treatment with recombinant factor VIIa.

Frequently, severe liver disease is associated with moderate prolongation of bleeding time that is not corrected by either vitamin K or plasma replacement. Desmopressin (0.3 µg/kg IV) is effective in shortening bleeding time and is used effectively to augment hemostasis before liver biopsy. In clinical trials of adults, recombinant factor VIIa has not been shown to be effective for the treatment of bleeding caused by severe liver disease.

Chapter **482**

Acquired Inhibitors of Coagulation

J. Paul Scott

Acquired circulating anticoagulants (inhibitors) are antibodies that react or crossreact with clotting factors or components used in coagulation screening tests (phospholipids), thereby prolonging screening tests, such as prothrombin time and partial thromboplastin time. Some of these anticoagulants are autoantibodies that react with phospholipid and thereby interfere with clotting in vitro but not in vivo. The most common form of these antiphospholipid antibodies has been referred to as the *lupus anticoagulant* (see Chapter 476.1). This anticoagulant is found in patients with systemic lupus erythematosus (see Chapter 158), in those with other collagen-vascular diseases, and in association with HIV. In otherwise healthy children, spontaneous lupus-like inhibitors have developed transiently after incidental viral infection. These transient inhibitors are usually not associated with either bleeding or thrombosis.

Although the classic lupus anticoagulant is more often associated with a predisposition to thrombosis than with bleeding symptoms, bleeding symptoms in a patient with the lupus anticoagulant may be caused by thrombocytopenia, as a manifestation of the antiphospholipid syndrome or of lupus itself, or, rarely, by a coexistent specific autoantibody against prothrombin (factor II). This antiprothrombin antibody does not inactivate prothrombin, but causes accelerated clearance of the protein, resulting in low levels of prothrombin.

Rarely, antibodies may arise spontaneously against a specific clotting factor, such as factor VIII or von Willebrand factor, similar to those seen more frequently in elderly patients. These patients are prone to excessive hemorrhage and may require specific treatment. In patients with a hereditary deficiency of a clotting factor (factor VIII or factor IX), antibodies may develop after exposure to transfused factor concentrates. These hemophilic inhibitory antibodies are discussed in Chapter 479.1.

LABORATORY FINDINGS

Inhibitors against specific coagulation factors usually affect factors VIII, IX, and XI, or, rarely, prothrombin. Depending on the target of the antibody, prothrombin time, partial thromboplastin time, or both may be prolonged. The mechanism by which the inhibitory antibody functions determines whether mixing patient plasma with normal plasma will normalize (correct) the clotting time. Patient plasma containing antibodies directed against the active site of the clotting factor (factor VIII or factor IX) will not correct on 1 : 1 mixing with normal plasma, whereas antibodies that lead to increased clearance of the factor (prothrombin) will correct on 1 : 1 mixing. Specific factor assays are used to determine which factor is involved.

TREATMENT

Management of the bleeding patient with an inhibitor against factor VIII or IX is the same as for the patient with hemophilia who has an alloantibody against factor VIII or factor IX. Infusions of recombinant factor VIIa or activated prothrombin complex concentrate may be needed to control significant bleeding. Immunosuppressive agents have used off-label to treat the inhibitor or reduce titers. Acute bleeding caused by an antiprothrombin antibody can often be treated with a plasma infusion and may benefit from a short course of corticosteroid therapy.

Asymptomatic spontaneous inhibitors that arise after a viral infection tend to disappear within a few weeks to months. Inhibitors seen with an underlying disease, such as systemic lupus erythematosus, often disappear when the primary disease is effectively treated.

Chapter **483**

Disseminated Intravascular Coagulation

J. Paul Scott and Leslie J. Raffini

Thrombotic microangiopathy refers to a heterogeneous group of conditions, including disseminated intravascular coagulation (DIC), that result in consumption of clotting factors, platelets, and anticoagulant proteins. Consequences of this process include widespread intravascular deposition of fibrin, leading to tissue ischemia and necrosis, a generalized hemorrhagic state, and hemolytic anemia.

ETIOLOGY

Any life-threatening severe systemic disease (Table 483-1) associated with hypoxia, acidosis, tissue necrosis, shock, and/or endothelial damage may trigger DIC. Better understanding of the pathophysiology of hemostasis has lead to an appreciation of the critical interaction of the coagulation pathways with the innate immune system and inflammatory response that likely contributes to the widespread dysregulation present in DIC. Activation and release of cytokines and chemokines alter endothelial function to a more prothrombotic state, enhancing the formation of microvascular thromboses, with resultant consumption of pro- and anticoagulant proteins. Excessive activation of clotting consumes both the physiologic anticoagulants (protein C, protein S, and antithrombin III) and procoagulants, resulting in a deficiency of factor V, factor VIII, prothrombin, fibrinogen, and platelets. Commonly, the clinical result of this sequence of events is hemorrhage. The hemostatic dysregulation may also result in thromboses in the skin, kidneys, and other organs.

CLINICAL MANIFESTATIONS

DIC accompanies a severe systemic disease process, usually with shock. Bleeding frequently first occurs from sites of venipuncture or surgical incision. The skin may show petechiae and ecchymoses. Tissue necrosis may involve many organs and can be most spectacularly seen as infarction of large areas of skin, subcutaneous tissue, or kidneys. Anemia caused by hemolysis may develop rapidly, owing to microangiopathic hemolytic anemia.

LABORATORY FINDINGS

There is no well-defined sequence of events. Certain coagulation factors (factors II, V, and VIII, and fibrinogen) and platelets may be consumed by the ongoing intravascular clotting process, with resultant prolongation of the prothrombin, partial thromboplastin, and thrombin times. Platelet counts may be profoundly depressed. The blood smear may contain fragmented, burr- and helmet-shaped red blood cells (schistocytes). In addition, because the fibrinolytic mechanism is activated, fibrinogen degradation products (D-dimers) appear in the blood. The D-dimer is formed by fibrinolysis of a crosslinked fibrin clot. The D-dimer assay is as sensitive as the fibrinogen degradation product test and more specific for activation of coagulation and fibrinolysis.

TREATMENT

The first 2 steps in the treatment of DIC are the most critical: (a) treat the trigger that caused DIC and (b) restore normal homeostasis by correcting the shock, acidosis, and hypoxia that usually complicate DIC. If the underlying problem can be controlled and the patient stabilized, bleeding quickly ceases, and there is improvement of the abnormal laboratory findings. Blood components are used for replacement therapy in patients with hemorrhage and may consist of platelet infusions (for thrombocytopenia), cryoprecipitate (for hypofibrinogenemia), and/or fresh-frozen plasma (for replacement of other coagulation factors and natural inhibitors).

The role of heparin in DIC is limited to patients who have vascular thrombosis in association with DIC or who require prophylaxis because they are at high risk for venous thromboembolism. Such individuals should be treated as outlined in Chapter 479, with careful attention to replacement therapy to maintain an adequate platelet count and thus limit bleeding complications.

Table 483-1 Causes of Disseminated Intravascular Coagulation

INFECTIOUS
Meningococcemia (purpura fulminans)
Bacterial sepsis (staphylococcal, streptococcal, *Escherichia coli*, *Salmonella*)
Rickettsia (Rocky Mountain spotted fever)
Virus (cytomegalovirus, herpes simplex, hemorrhagic fevers)
Malaria
Fungus
TISSUE INJURY
Central nervous system trauma (massive head injury)
Multiple fractures with fat emboli
Crush injury
Profound shock or asphyxia
Hypothermia or hyperthermia
Massive burns
MALIGNANCY
Acute promyelocytic leukemia
Acute monoblastic or promyelocytic leukemia
Widespread malignancies (neuroblastoma)
VENOM OR TOXIN
Snake bites
Insect bites
MICROANGIOPATHIC DISORDERS
"Severe" thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome
Giant hemangioma (Kasabach-Merritt syndrome)
GASTROINTESTINAL DISORDERS
Fulminant hepatitis
Ischemic bowel
Pancreatitis
HEREDITARY THROMBOTIC DISORDERS
Antithrombin III deficiency
Homozygous protein C deficiency
NEWBORN
Maternal toxemia
Bacterial or viral sepsis (group B streptococcus, herpes simplex)
Abruptio placenta
Severe respiratory distress syndrome
Necrotizing enterocolitis
Erythroblastosis fetalis
Fetal demise of a twin
MISCELLLANEOUS
Severe acute graft rejection
Acute hemolytic transfusion reaction
Severe collagen-vascular disease
Kawasaki disease
Heparin-induced thrombosis
Infusion of "activated" prothrombin complex concentrates
Hyperpyrexia/encephalopathy, hemorrhagic shock syndrome

Chapter 484

Platelet and Blood Vessel Disorders

J. Paul Scott

MEGAKARYOPOIESIS

Platelets are nonnucleated cellular fragments produced by megakaryocytes within the bone marrow and other tissues. Megakaryocytes are large polyploid cells. When the megakaryocyte approaches maturity, budding of the cytoplasm occurs and large numbers of platelets are liberated. Platelets circulate with a life span of 10-14 days. **Thrombopoietin** (TPO) is the primary growth factor that controls platelet production (Fig. 484-1). Levels of TPO appear to correlate inversely with platelet number and megakaryocyte mass. Levels of TPO are highest in the thrombocytopenic states associated with decreased marrow megakaryopoiesis and may be variable in states of increased platelet production.

The platelet plays multiple hemostatic roles. The platelet surface possesses a number of important receptors for adhesive proteins, including von Willebrand factor (VWF) and fibrinogen, as well as receptors for agonists that trigger platelet aggregation, such as thrombin, collagen, and adenosine diphosphate (ADP). After injury to the blood vessel wall, the extracellular matrix containing adhesive and procoagulant proteins is exposed. Subendothelial collagen binds VWF. VWF undergoes a conformational change that induces binding of the platelet glycoprotein Ib (GPIb) complex, the VWF receptor. This process is called *platelet adhesion*. Platelets then undergo activation. During the process of activation, the platelets generate thromboxane A_2 from arachidonic acid via the enzyme cyclooxygenase. After activation, platelets release agonists, such as ADP, adenosine triphosphate (ATP), Ca^{2+}, serotonin, and coagulation factors, into the surrounding milieu. Binding of VWF to the GPIb complex triggers a complex signaling cascade that results in activation of the fibrinogen receptor, the major platelet integrin glycoprotein αIIb-β_3 (GPIIb-IIIa). Circulating fibrinogen binds to its receptor on the activated platelets, complex linking platelets together in a process called *aggregation*. This series of events forms a hemostatic plug at the site of vascular injury. The serotonin and histamine that are liberated during activation increase local vasoconstriction. In addition to acting in concert with the vessel wall to form the platelet plug, the platelet provides the catalytic surface on which coagulation factors assemble and eventually generate thrombin through a sequential series of enzymatic cleavages. Last, the platelet contractile proteins and cytoskeleton mediate clot retraction.

THROMBOCYTOPENIA

The normal platelet count is 150-450 × 109/L. *Thrombocytopenia* refers to a reduction in platelet count to <150 × 10^9/L. Causes of thrombocytopenia include decreased production on either a congenital or an acquired basis, sequestration of the platelets within an enlarged spleen or other organ, and increased destruction of normally synthesized platelets on either an immune or a nonimmune basis (see Chapter 475; Tables 484-1 and 484-2 and Fig. 484-2).

Bibliography is available at Expert Consult.

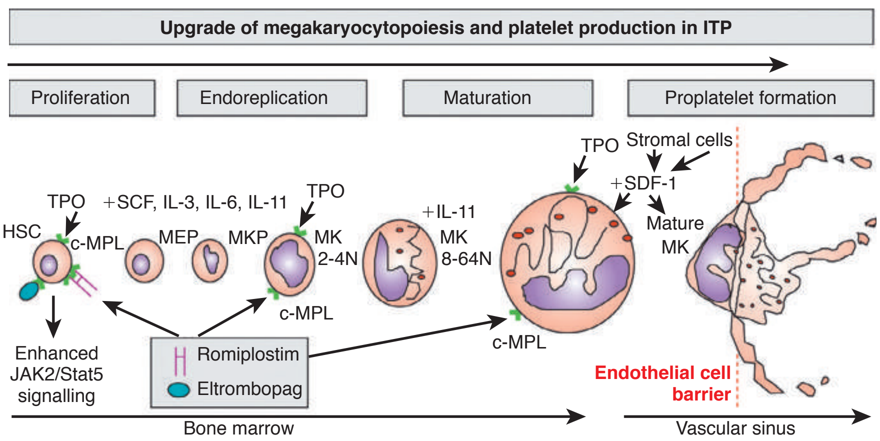

Figure 484-1 **Scheme of megakaryocytopoiesis and platelet production in idiopathic thrombocytopenic purpura.** Hematopoietic stem cells (HSC) are mobilized and megakaryocyte (MK) and erythroid progenitors (MEP) accumulate with MK-committed progenitors (MKP) giving rise to mature MKs under control of thrombopoietin (TPO) working with chemokines, cytokines, and growth factors, including stem cell factor (SCF) and interleukin (IL)-3, IL-6, and IL-11. Endoreplication results in ploidy changes in MKs and increased chromosome number (up to 64N). Mature MKs migrate to the endothelial cell barrier delimiting the vascular sinus and, under the influence of stromal-derived factor-1 (SDF-1), give rise to proplatelets that protrude into the circulation and produce large numbers of platelets under hemodynamic determinants. Therapeutically given romiplostim and eltrombopag enter the marrow and join with TPO to stimulate megakaryocytopoiesis and platelet production. *(From Nurden AT, Viallard JF, Nurden P: New-generation drugs that stimulate platelet production in chronic immune thrombocytopenic purpura*, Lancet *373:1562–1568, 2009, p. 1563.)*

Table 484-1 Differential Diagnosis of Thrombocytopenia in Children and Adolescents

DESTRUCTIVE THROMBOCYTOPENIAS

Primary Platelet Consumption Syndromes

Immune thrombocytopenias
- Acute and chronic ITP
- Autoimmune diseases with chronic ITP as a manifestation
  - Cyclic thrombocytopenia
  - Autoimmune lymphoproliferative syndrome and its variants
  - Systemic lupus erythematosus
  - Evans syndrome
  - Antiphospholipid antibody syndrome
  - Neoplasia-associated immune thrombocytopenia
- Thrombocytopenia associated with HIV
- Neonatal immune thrombocytopenia
  - Alloimmune
  - Autoimmune (e.g., maternal ITP)
- Drug-induced immune thrombocytopenia (including heparin-induced thrombocytopenia)
- Posttransfusion purpura
- Allergy and anaphylaxis
- Posttransplant thrombocytopenia

Nonimmune thrombocytopenias
- Thrombocytopenia of infection
  - Bacteremia or fungemia
  - Viral infection
  - Protozoan
- Thrombotic microangiopathic disorders
  - Hemolytic-uremic syndrome
  - Eclampsia, HELLP syndrome
  - Thrombotic thrombocytopenic purpura
  - Bone marrow transplantation-associated microangiopathy
  - Drug-induced
- Platelets in contact with foreign material
- Congenital heart disease
- Drug-induced via direct platelet effects (ristocetin, protamine)
- Type 2B VWD or platelet-type VWD

Combined Platelet and Fibrinogen Consumption Syndromes
- Disseminated intravascular coagulation
- Kasabach-Merritt syndrome
- Virus-associated hemophagocytic syndrome

IMPAIRED PLATELET PRODUCTION
- Hereditary disorders
- Acquired disorders
  - Aplastic anemia
  - Myelodysplastic syndrome
  - Marrow infiltrative process—neoplasia
  - Osteopetrosis
  - Nutritional deficiency states (iron, folate, vitamin B_{12}, anorexia nervosa)
  - Drug- or radiation-induced thrombocytopenia
  - Neonatal hypoxia or placental insufficiency

SEQUESTRATION
- Hypersplenism
- Hypothermia
- Burns

HELLP, hemolysis, elevated liver enzymes, and low platelets; HIV, human immunodeficiency virus; ITP, immune thrombocytopenic purpura; VWD, von Willebrand disease.

484.1 Idiopathic (Autoimmune) Thrombocytopenic Purpura

J. Paul Scott

The most common cause of acute onset of thrombocytopenia in an otherwise well child is (autoimmune) idiopathic thrombocytopenic purpura (ITP).

EPIDEMIOLOGY

In a small number of children, estimated at 1 in 20,000, 1-4 wk after exposure to a common viral infection, an autoantibody directed against the platelet surface develops with resultant sudden onset of thrombocytopenia. A recent history of viral illness is described in 50-65% of cases of childhood ITP. The peak age is 1-4 yr, although the age ranges from early in infancy to the elderly. In childhood, males and females are equally affected. ITP seems to occur more often in late winter and spring after the peak season of viral respiratory illness.

PATHOGENESIS

Why some children develop the acute presentation of an autoimmune disease is unknown. The exact antigenic target for most such antibodies in most cases of childhood acute ITP remains undetermined. Although in chronic ITP, many patients demonstrate antibodies against the platelet glycoprotein complexes, αIIb-β_3 and GPIb. After binding of the antibody to the platelet surface, circulating antibody-coated platelets are recognized by the Fc receptor on splenic macrophages, ingested, and destroyed. Most common viruses have been described in association with ITP, including Epstein-Barr virus (see Chapter 254) and HIV (see Chapter 276). Epstein-Barr virus-related ITP is usually of short duration and follows the course of infectious mononucleosis. HIV-associated ITP is usually chronic. In some patients ITP appears to arise in children infected with *Helicobacter pylori* or rarely following vaccines.

CLINICAL MANIFESTATIONS

The classic presentation of ITP is a previously healthy 1-4 yr old child who has sudden onset of generalized petechiae and purpura. The parents often state that the child was fine yesterday and now is covered with bruises and purple dots. There may be bleeding from the gums and mucous membranes, particularly with profound thrombocytopenia (platelet count $<10 \times 10^9$/L). There is a history of a preceding viral infection 1-4 wk before the onset of thrombocytopenia. Findings on physical examination are normal, other than the finding of petechiae and purpura. Splenomegaly, lymphadenopathy, bone pain, and pallor are rare. An easy to use classification system has been proposed from the United Kingdom to characterize the severity of bleeding in ITP on the basis of symptoms and signs, but not platelet count:

1. No symptoms
2. Mild symptoms: bruising and petechiae, occasional minor epistaxis, very little interference with daily living
3. Moderate: more severe skin and mucosal lesions, more troublesome epistaxis and menorrhagia
4. Severe: bleeding episodes—menorrhagia, epistaxis, melena—requiring transfusion or hospitalization, symptoms interfering seriously with the quality of life

The presence of abnormal findings such as hepatosplenomegaly, bone or joint pain, remarkable lymphadenopathy other cytopenias, or congenital anomalies suggests other diagnoses (leukemia, syndromes). When the onset is insidious, especially in an adolescent, chronic ITP or the possibility of a systemic illness, such as systemic lupus erythematosus (SLE), is more likely.

OUTCOME

Severe bleeding is rare (<3% of cases in 1 large international study). In 70-80% of children who present with acute ITP, spontaneous resolution occurs within 6 mo. Therapy does not appear to affect the natural history of the illness. Fewer than 1% of patients develop an intracranial hemorrhage. Those who favor interventional therapy argue that the objective of early therapy is to raise the platelet count to $>20 \times 10^9$/L and prevent the rare development of intracranial hemorrhage. There is no evidence that therapy prevents serious bleeding. Approximately 20% of children who present with acute ITP go on to have chronic ITP. The outcome/prognosis may be related more to age, as ITP in younger children is more likely to resolve whereas the development of chronic ITP in adolescents approaches 50%.

LABORATORY FINDINGS

Severe thrombocytopenia (platelet count $<20 \times 10^9$/L) is common, and platelet size is normal or increased, reflective of increased platelet turnover (Fig. 484-3). In acute ITP, the hemoglobin value, white blood cell (WBC) count, and differential count should be normal. Hemoglobin may be decreased if there have been profuse nosebleeds or menorrhagia. Bone marrow examination shows normal granulocytic and erythrocytic series, with characteristically normal or increased

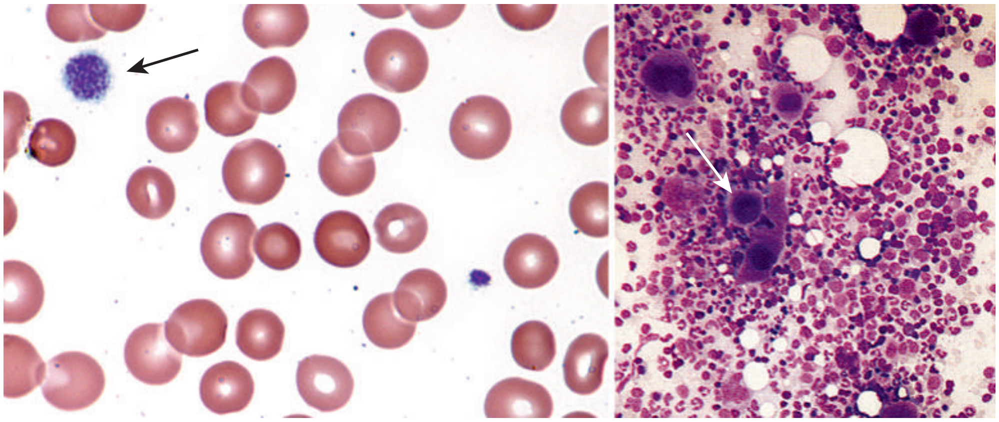

Figure 484-3 Blood smear and bone marrow aspirate from a child who had ITP showing large platelets (blood smear *[left]*) and increased numbers of megakaryocytes, many of which appear immature (bone marrow aspirate *[right]*). *(From Blanchette V, Bolton-Maggs P: Childhood immune thrombocytopenic purpura: diagnosis and management,* Pediatr Clin North Am *55:393–420, 2008, p. 400, Fig. 4.)*

numbers of megakaryocytes. Some of the megakaryocytes may appear to be immature and are reflective of increased platelet turnover. **Indications for bone marrow** aspiration/biopsy include an abnormal WBC count or differential or unexplained anemia as well as findings on history and physical examination suggestive of a bone marrow failure syndrome or malignancy. Other laboratory tests should be performed as indicated by the history and physical examination. HIV studies should be done in at-risk populations, especially sexually active teens. Platelet antibody testing is seldom useful in acute ITP. A direct antiglobulin test (Coombs) should be done if there is unexplained anemia to rule out Evans syndrome (autoimmune hemolytic anemia and thrombocytopenia) (see Chapter 458) or before instituting therapy with IV anti-D.

DIAGNOSIS/DIFFERENTIAL DIAGNOSIS

The well-appearing child with moderate to severe thrombocytopenia, an otherwise normal complete blood cell count (CBC), and normal findings on physical examination has a limited differential diagnosis that includes exposure to medication that induces drug-dependent antibodies, splenic sequestration because of previously unappreciated portal hypertension, and, rarely, early aplastic processes, such as Fanconi anemia (see Chapter 468). Other than congenital thrombocytopenia syndromes (see Chapter 484.8), such as thrombocytopenia-absent radius (TAR) syndrome and MYH9-related thrombocytopenia, most marrow processes that interfere with platelet production eventually cause abnormal synthesis of red blood cells (RBCs) and WBCs, and therefore manifest diverse abnormalities on the CBC. Disorders that cause increased platelet destruction on a nonimmune basis are usually serious systemic illnesses with obvious clinical findings (e.g., hemolytic-uremic syndrome [HUS], disseminated intravascular coagulation [DIC]) (see Table 483-1 in Chapter 483, and Fig. 484-2). Patients on heparin may develop heparin-induced thrombocytopenia. Isolated enlargement of the spleen suggests the potential for hypersplenism owing to either liver disease or portal vein thrombosis. Autoimmune thrombocytopenia may be an initial manifestation of SLE, HIV infection, common variable immunodeficiency, and, rarely, lymphoma or autoimmune lymphoproliferative syndrome. Wiskott-Aldrich syndrome (WAS; Chapter 126.2) must be considered in young males found to have thrombocytopenia with small platelets, particularly if there is a history of eczema and recurrent infection.

TREATMENT

There are no data showing that treatment affects either short- or long-term clinical outcome of ITP. Many patients with new-onset ITP have mild symptoms, with findings limited to petechiae and purpura on the skin, despite severe thrombocytopenia. Compared with untreated control subjects, treatment appears to be capable of inducing a more rapid rise in platelet count to the theoretically safe level of $>20 \times 10^9$/L, although there are no data indicating that early therapy prevents intracranial hemorrhage. Antiplatelet antibodies bind to transfused platelets as well as they do to autologous platelets. Thus, platelet transfusion in ITP is usually contraindicated unless life-threatening bleeding is present. Initial approaches to the management of ITP include the following:

1. No therapy other than education and counseling of the family and patient for patients with minimal, mild, and moderate symptoms, as defined earlier. This approach emphasizes the usually benign nature of ITP and avoids the therapeutic roller coaster that ensues once interventional therapy is begun. This approach is far less costly, and side effects are minimal.
2. Per the American Society of Hematology Guidelines: "A single dose of IVIG [intravenous immunoglobulin] (0.8-1.0 g/kg) or a short course of corticosteroids should be used as first-line treatment." IVIG at a dose of 0.8-1.0 g/kg/day for 1-2 days induces a rapid rise in platelet count (usually $>20 \times 10^9$/L) in 95% of patients within 48 hr. IVIG appears to induce a response by downregulating Fc-mediated phagocytosis of antibody-coated platelets. IVIG therapy is both expensive and time-consuming to administer. Additionally, after infusion, there is a high frequency of headaches and vomiting, suggestive of IVIG-induced aseptic meningitis.
3. Prednisone. Corticosteroid therapy has been used for many years to treat acute and chronic ITP in adults and children. Doses of prednisone of 1-4 mg/kg/24 hr appear to induce a more rapid rise in platelet count than in untreated patients with ITP. Corticosteroid therapy is usually continued for short course until a rise in platelet count to $>20 \times 10^9$/L has been achieved to avoid the long-term side effects of corticosteroid therapy, especially growth failure, diabetes mellitus, and osteoporosis.
4. Intravenous anti-D therapy. For Rh-positive patients, IV anti-D at a dose of 50-75 μg/kg causes a rise in platelet count to $>20 \times 10^9$/L in 80-90% of patients within 48-72 hr. When given to Rh-positive individuals, IV anti-D induces mild hemolytic anemia. RBC-antibody complexes bind to macrophage Fc receptors and interfere with platelet destruction, thereby causing a rise in platelet count. IV anti-D is ineffective in Rh-negative patients. Rare life-threatening episodes of intravascular hemolysis have occurred in children and adults following infusion of IV anti-D.

Each of these medications may be used to treat ITP exacerbations, which commonly occur several weeks after an initial course of therapy. In the special case of intracranial hemorrhage, multiple modalities should be used, including platelet transfusion, IVIG, high-dose corticosteroids, and prompt consultation by neurosurgery and surgery.

There is no consensus regarding the management of acute childhood ITP, except that patients who are bleeding significantly (less than 5% of children with ITP) should be treated. Intracranial hemorrhage

remains rare, and there are no data showing that treatment actually reduces its incidence.

The role of splenectomy in ITP should be reserved for 1 of 2 circumstances. The older child (≥4 yr) with severe ITP that has lasted >1 yr (chronic ITP) and whose symptoms are not easily controlled with therapy is a candidate for splenectomy. Splenectomy must also be considered when life-threatening hemorrhage (intracranial hemorrhage) complicates acute ITP, if the platelet count cannot be corrected rapidly with transfusion of platelets and administration of IVIG and corticosteroids. Splenectomy is associated with a lifelong risk of overwhelming postsplenectomy infection caused by encapsulated organisms, increased risk of thrombosis, and the potential development of pulmonary hypertension in adulthood. As an alternative to splenectomy, rituximab has been used off-label in children to treat chronic ITP. In 30-40% of children, rituximab has induced a partial or complete remission.

CHRONIC AUTOIMMUNE THROMBOCYTOPENIC PURPURA

Approximately 20% of patients who present with acute ITP have persistent thrombocytopenia for **>12 mo** and are said to have chronic ITP. At that time, a careful reevaluation for associated disorders should be performed, especially for autoimmune disease, such as SLE; chronic infectious disorders, such as HIV; and nonimmune causes of chronic thrombocytopenia, such as type 2B and platelet-type von Willebrand disease, X-linked thrombocytopenia, autoimmune lymphoproliferative syndrome, common variable immunodeficiency syndrome, autosomal macrothrombocytopenia, and WAS (also X-linked). The presence of coexisting *H. pylori* infection should be considered and, if found, treated. Therapy should be aimed at controlling symptoms and preventing serious bleeding. In ITP, the spleen is the primary site of both antiplatelet antibody synthesis and platelet destruction. Splenectomy is successful in inducing complete remission in 64-88% of children with chronic ITP. This effect must be balanced against the lifelong risk of overwhelming postsplenectomy infection. This decision is often affected by quality of life issues, as well as the ease with which the child can be managed using medical therapy, such as IVIG, corticosteroids, IV anti-D, or rituximab. Two effective agents that act to stimulate thrombopoiesis, romiplastin and eltrombopag (see Fig. 484-1), are approved by the FDA to treat adults with chronic ITP. Preliminary data using thrombopoietic agents in children are encouraging.

Bibliography is available at Expert Consult.

484.2 Drug-Induced Thrombocytopenia

J. Paul Scott

A number of drugs are associated with immune thrombocytopenia as the result of either an immune process or megakaryocyte injury. Some common drugs used in pediatrics that cause thrombocytopenia include valproic acid, phenytoin, carbamazepine, sulfonamides, vancomycin, and trimethoprim-sulfamethoxazole. Heparin-induced thrombocytopenia (and, rarely, an associated thrombosis) is seldom seen in pediatrics, but it occurs when, after exposure to heparin, the patient has an antibody directed against the heparin–platelet factor 4 complex. Recommended treatment for heparin-induced thrombocytopenia in adults includes argatroban, lepirudin, or danaparoid.

Bibliography is available at Expert Consult.

484.3 Nonimmune Platelet Destruction

J. Paul Scott

The syndromes of DIC (see Chapter 483), HUS (see Chapters 484.4 and 518), and thrombotic thrombocytopenic purpura (TTP) (see Chapter 484.5) share the hematologic picture of a thrombotic microangiopathy in which there is RBC destruction and consumptive thrombocytopenia caused by platelet and fibrin deposition in the microvasculature. The microangiopathic hemolytic anemia is characterized by the presence of RBC fragments, including helmet cells, schistocytes, spherocytes, and burr cells.

484.4 Hemolytic-Uremic Syndrome

See Chapter 518.

484.5 Thrombotic Thrombocytopenic Purpura

J. Paul Scott

TTP is a rare pentad of **fever, microangiopathic hemolytic anemia, thrombocytopenia, abnormal renal function,** and **central nervous system changes** that is clinically similar to HUS, although TTP can be congenital, it usually presents in adults and occasionally in adolescents. Microvascular thrombi within the central nervous system cause subtle, shifting neurologic signs that vary from changes in affect and orientation to aphasia, blindness, and seizures. Initial manifestations are often nonspecific (weakness, pain, emesis); prompt recognition of this disorder is critical. Laboratory findings provide important clues to the diagnosis and show microangiopathic hemolytic anemia characterized by morphologically abnormal RBCs, with schistocytes, spherocytes, helmet cells, and an elevated reticulocyte count in association with thrombocytopenia. Coagulation studies are usually nondiagnostic. Blood urea nitrogen and creatinine are sometimes elevated. The treatment of TTP is plasmapheresis (plasma exchange), which is effective in 80-95% of cases. Treatment with plasmapheresis should be instituted on the basis of thrombocytopenia and microangiopathic hemolytic anemia even if other symptoms are not yet present. Rituximab, corticosteroids, and splenectomy are reserved for refractory cases.

The majority of cases of TTP are caused by an autoantibody–mediated deficiency of a metalloproteinase (ADAMTS-13) that is responsible for cleaving the high-molecular-weight multimers of VWF and appears to play a pivotal role in the evolution of the thrombotic microangiopathy. In contrast, levels of the metalloproteinase in HUS are usually normal. **Congenital deficiency** of the metalloproteinase causes rare familial cases of TTP/HUS, usually manifested as recurrent episodes of thrombocytopenia, hemolytic anemia, and renal involvement, with or without neurologic changes, that often present in infancy after an intercurrent illness. Abnormalities of the complement system have now also been implicated in rare cases of familial TTP. ADAMTS-13 deficiency can be treated by repeated infusions of fresh-frozen plasma.

Bibliography is available at Expert Consult.

484.6 Kasabach-Merritt Syndrome

J. Paul Scott

See also Chapter 650.

The association of a giant hemangioma with localized intravascular coagulation causing thrombocytopenia and hypofibrinogenemia is called *Kasabach-Merritt syndrome.* In most patients, the site of the hemangioma is obvious, but retroperitoneal and intraabdominal hemangiomas may require body imaging for detection. Inside the hemangioma there is platelet trapping and activation of coagulation, with fibrinogen consumption and generation of fibrin(ogen) degradation products. Arteriovenous malformation within the lesions can cause heart failure. Pathologically, Kasabach-Merritt syndrome appears to develop more often as a result of a kaposiform hemangioendothelioma

or tufted hemangioma rather than a simple hemangioma. The peripheral blood smear shows microangiopathic changes. Multiple modalities have been used to treat Kasabach-Merritt syndrome, including propranolol, surgical excision (if possible), laser photocoagulation, high-dose corticosteroids, local radiation therapy, antiangiogenic agents, such as interferon-α_2, and vincristine. Over time, most patients who present in infancy have regression of the hemangioma. Treatment of the associated coagulopathy may benefit from a trial of antifibrinolytic therapy with ε-aminocaproic acid (Amicar).

484.7 Sequestration

J. Paul Scott

Thrombocytopenia develops in individuals with massive splenomegaly because the spleen acts as a sponge for platelets and sequesters large numbers. Most such patients also have mild leukopenia and anemia on CBC. Individuals who have thrombocytopenia caused by splenic sequestration should undergo a work-up to diagnose the etiology of splenomegaly, including infectious, inflammatory, infiltrative, neoplastic, obstructive, and hemolytic causes.

484.8 Congenital Thrombocytopenic Syndromes

J. Paul Scott

See Table 484-2.

Congenital amegakaryocytic thrombocytopenia (CAMT) usually manifests within the 1st few days to week of life, when the child presents with petechiae and purpura caused by profound thrombocytopenia. CAMT is caused by a rare defect in hematopoiesis as a result of a mutation in the stem cell TPO receptor (MPL). Other than skin and mucous membrane abnormalities, findings on physical examination are normal. Examination of the bone marrow shows an absence of megakaryocytes. These patients often progress to marrow failure (aplasia) over time. Hematopoietic stem cell transplantation is curative.

TAR syndrome consists of thrombocytopenia (absence or hypoplasia of megakaryocytes) that presents in early infancy with bilateral radial anomalies of variable severity, ranging from mild changes to marked limb shortening (Fig. 484-4). Many such individuals also have other skeletal abnormalities of the ulna, radius, and lower extremities. Thumbs are present. Intolerance to cow's milk formula (present in 50%) may complicate management by triggering gastrointestinal bleeding, increased thrombocytopenia, eosinophilia, and a leukemoid reaction. The thrombocytopenia of TAR syndrome frequently remits over the 1st few yrs of life. The molecular basis of TAR syndrome remains to be defined. A few patients have been reported to have a syndrome of **amegakaryocytic thrombocytopenia with radioulnar synostosis** caused by a mutation in the *HOXA11* gene. Different from TAR syndrome, this mutation causes marrow aplasia.

WAS is characterized by thrombocytopenia, with tiny platelets, eczema, and recurrent infection as a consequence of immune deficiency (see Chapter 126.2). WAS is inherited as an X-linked disorder, and the gene for WAS has been sequenced. The WAS protein appears to play an integral role in regulating the cytoskeletal architecture of both platelets and T lymphocytes in response to receptor-mediated cell signaling. The WAS protein is common to all cells of hematopoietic lineage. Molecular analysis of families with X-linked thrombocytopenia has shown that many affected members have a point mutation within the WAS gene, whereas individuals with the full manifestation of WAS have large gene deletions. Examination of the bone marrow in WAS shows the normal number of megakaryocytes, although they may have bizarre morphologic features. Transfused platelets have a normal life span. Splenectomy often corrects the thrombocytopenia, suggesting that the platelets formed in WAS have accelerated destruction. After splenectomy, these patients are at increased risk for overwhelming infection and require lifelong antibiotic prophylaxis against encapsulated organisms. Approximately 5-15% of patients with WAS develop lymphoreticular malignancies. Successful hematopoietic stem cell transplantation cures WAS. **X-linked macrothrombocytopenia** and **dyserythropoiesis** have been linked to mutations in the *GATA-1* gene, an erythroid and megakaryocytic transcription factor.

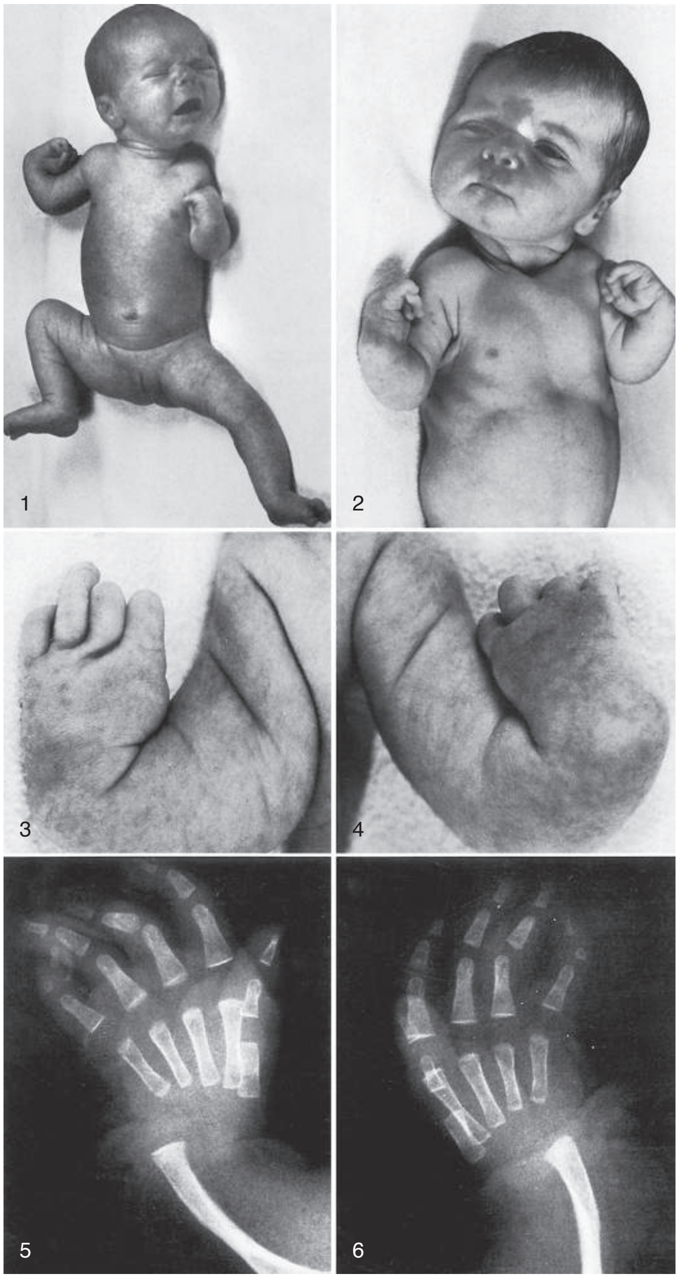

Figure 484-4 A newborn, the first child of young, healthy parents, with fully expressed TAR syndrome, including thrombocytopenia, hypereosinophilia, and anemia. Hypoplasia of the distal humeri and the shoulder girdles, bilateral hip dysplasia, mild talipes calcaneus, and clinodactyly of both little fingers are seen. This patient had a pronounced allergy to cow's milk, with exposure followed by diarrhea, vomiting, and decreased weight and platelet count, making a cow's milk–free diet mandatory. A persistent depressed nasal bridge and development of pronounced bowed legs are seen. *(From Wiedemann H-R, Kunze J, Grosse F-R, editors:* Clinical syndromes, *ed 3, [English translation], London, 1997, Mosby-Wolfe, p. 430.)*

MYH9-related thrombocytopenia: A diverse number of hereditary thrombocytopenia syndromes, given names such as Sebastian, Epstein,

May-Hegglin, and Fechtner syndromes, are characterized by autosomal dominant macrothrombocytopenia, neutrophil inclusion bodies, and a variety of physical anomalies, including sensorineural deafness, renal disease, and/or eye disease. These have all been shown to be caused by different mutations in the *MYH9* gene (nonmuscle myosin-IIa heavy chain). The thrombocytopenia is usually mild and not progressive. Some other individuals with recessively inherited macrothrombocytopenia have abnormalities in chromosome 22q11. Mutations in the gene for glycoprotein Ibβ, an essential component of the platelet VWF receptor, can result in Bernard-Soulier syndrome (see Chapter 484.13).

Bibliography is available at Expert Consult.

484.9 Neonatal Thrombocytopenia

J. Paul Scott

See also Chapter 103.4.

Thrombocytopenia in the newborn rarely is indicative of a primary disorder of megakaryopoiesis but more often is the result of either systemic illness or transfer of maternal antibodies directed against fetal platelets (see Table 484-2). Neonatal thrombocytopenia often occurs in association with congenital viral infection, especially rubella; cytomegalovirus; protozoal infection, such as toxoplasmosis; syphilis; and perinatal bacterial infection, especially those caused by Gram-negative bacilli. Thrombocytopenia associated with DIC may be responsible for severe spontaneous bleeding. The constellation of marked thrombocytopenia and abnormal abdominal findings is common in necrotizing enterocolitis and other causes of necrotic bowel. Thrombocytopenia in an ill child requires a prompt search for viral and bacterial pathogens.

Antibody-mediated thrombocytopenia in the newborn occurs because of transplacental transfer of maternal antibodies directed against fetal platelets. Neonatal alloimmune thrombocytopenic purpura (NATP) is caused by the development of maternal antibodies against antigens present on fetal platelets that are shared with the father and recognized as foreign by the maternal immune system. This is the platelet equivalent of Rh disease of the newborn. The incidence of NATP is 1/4,000-5,000 live births. The clinical manifestations of NATP are those of an apparently well child who, within the 1st few days after delivery, has generalized petechiae and purpura. Laboratory studies show a normal maternal platelet count, yet moderate to severe thrombocytopenia in the newborn. Detailed review of the history should show no evidence of maternal thrombocytopenia. Up to 30% of infants with severe NATP may have intracranial hemorrhage, either prenatally or in the perinatal period. Unlike Rh disease, first pregnancies may be severely affected. Subsequent pregnancies are often more severely affected than the first.

The **diagnosis** of NATP is made by checking for the presence of maternal alloantibodies directed against the father's platelets. Specific studies can be done to identify the target alloantigen. The most common cause is incompatibility for the platelet alloantigen HPA-1a. Specific DNA sequence polymorphisms have been identified that permit informative prenatal testing to identify at-risk pregnancies. The differential diagnosis of NATP includes transplacental transfer of maternal antiplatelet autoantibodies (maternal ITP), and, more commonly, viral or bacterial infection.

Treatment of NATP requires the administration of IVIG prenatally to the mother. Therapy usually begins in the 2nd trimester and is continued throughout the pregnancy. Fetal platelet count can be monitored by percutaneous umbilical blood sampling. Delivery should be performed by cesarean section. After delivery, if severe thrombocytopenia persists, transfusion of 1 unit of platelets that share the maternal alloantigens (e.g., washed maternal platelets) will cause a rise in platelet counts to provide effective hemostasis. After there has been 1 affected child, genetic counseling is critical to inform the parents of the high risk of thrombocytopenia in subsequent pregnancies.

Children born to mothers with ITP **(maternal ITP)** appear to have a lower risk of serious hemorrhage than infants born with NATP, although severe thrombocytopenia may occur. The mother's preexisting platelet count may have some predictive value in that severe maternal thrombocytopenia before delivery appears to predict a higher risk of fetal thrombocytopenia. In mothers who have had splenectomy for ITP, the maternal platelet count may be normal and is not predictive of fetal thrombocytopenia.

Treatment includes prenatal administration of corticosteroids to the mother and administration of IVIG and sometimes corticosteroids to the infant after delivery. Thrombocytopenia in an infant, whether a result of NATP or maternal ITP, usually resolves within 2-4 mo after delivery. The period of highest risk is the immediate perinatal period.

Two syndromes of congenital failure of platelet production often present in the newborn period. In **CAMT,** the newborn manifests petechiae and purpura shortly after birth. Findings on physical examination are otherwise normal. Megakaryocytes are absent from the bone marrow. This syndrome is caused by a mutation in the megakaryocyte TPO receptor that is essential for development of all hematopoietic cell lines. Pancytopenia eventually develops, and hematopoietic stem cell transplantation is curative. **TAR syndrome** consists of thrombocytopenia that presents in early infancy, with bilateral radial anomalies of variable severity, ranging from mild changes to marked limb shortening. Thumbs are present. In many such individuals, there are also other skeletal abnormalities of the lower extremities. Intolerance to cow's milk formula is present in 50% of patients. TAR syndrome frequently remits over the 1st few yr of life (see Chapter 484.8) (see Fig. 484-4).

484.10 Thrombocytopenia from Acquired Disorders Causing Decreased Production

J. Paul Scott and Veronica Flood

Disorders of the bone marrow that inhibit megakaryopoiesis usually affect RBC and WBC production. Infiltrative disorders, including malignancies, such as acute lymphocytic leukemia, histiocytosis, lymphomas, and storage disease, usually cause either abnormalities on physical examination (lymphadenopathy, hepatosplenomegaly, or masses) or abnormalities of the WBC count, or anemia. Aplastic processes may present as isolated thrombocytopenia, although there are usually clues on the CBC (leukopenia, neutropenia, anemia, or macrocytosis). Children with constitutional aplastic anemia (Fanconi anemia) often have abnormalities on examination, including radial anomalies, other skeletal anomalies, short stature, microcephaly, and hyperpigmentation. Bone marrow examination should be performed when thrombocytopenia is associated with abnormalities found on physical examination or on examination of the other blood cell lines.

484.11 Platelet Function Disorders

J. Paul Scott

Bleeding time and the platelet function analyzer (PFA-100) are the only commonly available tests to screen for abnormal platelet function. Bleeding time measures the interaction of platelets with the blood vessel wall and thus is affected by both platelet count and platelet function. The predictive value of bleeding time is problematic because bleeding time is dependent on a number of other factors, including the skill of the technician and the cooperation of the patient, often a challenge in the infant or young child. A normal bleeding time does not rule out a mild platelet function defect in a clinically symptomatic individual. The PFA-100 measures platelet adhesion and aggregation in whole blood at high shear when the blood is exposed to either

collagen-epinephrine or collagen-ADP. Results are reported as the closure time measured in sec. Many clinical laboratories have replaced bleeding time with the use of the PFA-100. Both the PFA-100 and bleeding time are sensitive to moderate/severe von Willebrand disease and platelet dysfunction. Both are variably insensitive to mild platelet function abnormalities and mild von Willebrand disease. The use of the PFA-100 as a screening test remains controversial and, like the bleeding time, lacks specificity. Bleeding time is the only commonly available test to assess platelet–vessel wall interaction. For patients with a positive history of bleeding suggestive of von Willebrand disease or platelet dysfunction, specific VWF testing and platelet function studies should be done, irrespective of the results of the bleeding time or PFA-100.

Platelet function in the clinical laboratory is currently measured using platelet aggregometry. In the aggregometer, agonists, such as collagen, ADP, ristocetin, epinephrine, arachidonic acid, and thrombin (or the thrombin receptor peptide), are added to platelet-rich plasma, and the clumping of platelets over time is measured by an automated machine. At the same time, other instruments measure the release of granular contents, such as ATP, from the platelets after activation. The ability of platelets to aggregate and their metabolic activity can be assessed simultaneously. When a patient is being evaluated for possible platelet dysfunction, it is critically important to exclude the presence of other exogenous agents and to study the patient, if possible, off all medications for 2 wk. Further evaluation using flow cytometric analysis or molecular testing are often necessary to make a more definitive diagnosis.

484.12 Acquired Disorders of Platelet Function

J. Paul Scott

A number of systemic illnesses are associated with platelet dysfunction, most commonly, liver disease, kidney disease (uremia), and disorders that trigger increased amounts of fibrin degradation products. These disorders frequently cause prolonged bleeding time and are often associated with other abnormalities of the coagulation mechanism. The most important element of management is to treat the primary illness. If treatment of the primary process is not feasible, infusions of desmopressin have been helpful in augmenting hemostasis and correcting bleeding time. In some patients, transfusions of platelets and/or cryoprecipitate have also been helpful in improving hemostasis.

Many drugs alter platelet function. The most commonly used drug in adults that alters platelet function is acetylsalicylic acid (aspirin). Aspirin irreversibly acetylates the enzyme cyclo-oxygenase, which is critical in the formation of thromboxane A_2. Aspirin usually causes moderate platelet dysfunction that becomes more prominent if there is another abnormality of the hemostatic mechanism. In children, commonly used drugs that affect platelet function include other nonsteroidal antiinflammatory drugs, valproic acid, and high-dose penicillin. Specific agents to inhibit platelet function therapeutically include those that block the platelet ADP receptor (clopidogrel) and αIIb-β_3 receptor antagonists, as well as aspirin.

484.13 Congenital Abnormalities of Platelet Function

J. Paul Scott

Severe platelet function defects usually present with petechiae and purpura shortly after birth, especially after vaginal delivery. Defects in the platelet GPIb complex (the VWF receptor) or the αIIb-β_3 complex (the fibrinogen receptor) cause severe congenital platelet dysfunction.

Bernard-Soulier syndrome, a severe congenital platelet function disorder, is caused by absence or severe deficiency of the VWF receptor (GPIb complex) on the platelet membrane. This syndrome is characterized by thrombocytopenia, with giant platelets and markedly prolonged bleeding time (>20 min) or PFA-100 closure time. Platelet aggregation tests show absent ristocetin-induced platelet aggregation, but normal aggregation to all other agonists. Ristocetin induces the binding of VWF to platelets and agglutinates platelets. Results of studies of VWF are normal. The GPIb complex interacts with the platelet cytoskeleton; a defect in this interaction is believed to be the cause of the large platelet size. Bernard-Soulier syndrome is inherited as an autosomal recessive disorder. Genetic mutations causing Bernard-Soulier syndrome are usually identified in the genes forming the GPIb complex of glycoproteins Ibα, Ibβ, V, and IX.

Glanzmann thrombasthenia is a congenital disorder associated with severe platelet dysfunction that yields prolonged bleeding time and a normal platelet count. Platelets have normal size and morphologic features on the peripheral blood smear, and closure times for PFA-100 or bleeding time are markedly abnormal. Aggregation studies show abnormal or absent aggregation with all agonists used except ristocetin, because ristocetin agglutinates platelets and does not require a metabolically active platelet. This disorder is caused by deficiency of the platelet fibrinogen receptor αIIb-β_3, the major integrin complex on the platelet surface that undergoes conformational changes by inside out signaling when platelets are activated. Fibrinogen binds to this complex when the platelet is activated and causes platelets to aggregate. Caused by identifiable mutations in the genes for αIIb or β_3, this disorder is inherited in an autosomal recessive manner. For both Bernard-Soulier syndrome and Glanzmann thrombasthenia, the diagnosis is confirmed by flow cytometric analysis of the patient's platelet glycoproteins.

Hereditary deficiency of platelet storage granules occurs in 2 well-characterized but rare syndromes that involve deficiency of intracytoplasmic granules. **Dense body deficiency** is characterized by absence of the granules that contain ADP, ATP, Ca^{2+}, and serotonin. This disorder is diagnosed by the finding that ATP is not released on platelet aggregation studies and ideally is characterized by electron microscopic studies. **Gray platelet syndrome** is caused by the absence of platelet α granules, resulting in large platelets that are large and appear gray on Wright stain of peripheral blood. In this rare syndrome, aggregation and release are absent with most agonists other than thrombin and ristocetin. Electron microscopic studies are diagnostic.

OTHER HEREDITARY DISORDERS OF PLATELET FUNCTION

Abnormalities in the pathways of platelet signaling/activation and release of granular contents cause a heterogeneous group of platelet function defects that are usually manifested as increased bruising, epistaxis, and/or menorrhagia. Symptoms may be subtle and are often made more obvious by high-risk surgery, such as tonsillectomy or adenoidectomy, or by administration of nonsteroidal antiinflammatory drugs. In the laboratory, bleeding time is variable and closure time as measured by the PFA-100 is frequently, but not always, prolonged. Platelet aggregation studies show deficient aggregation with 1 or 2 agonists and/or abnormal release of granular contents.

The formation of thromboxane from arachidonic acid after the activation of phospholipase is critical to normal platelet function. Deficiency or dysfunction of enzymes, such as cyclo-oxygenase and thromboxane synthase, which metabolize arachidonic acid, causes abnormal platelet function. In the aggregometer, platelets from such patients do not aggregate in response to arachidonic acid.

The most common platelet function defects are those characterized by variable bleeding time/PFA closure times and abnormal aggregation with 1 or 2 agonists, usually ADP and/or collagen. These patients have normal aggregation with thrombin receptor peptide. Some of these individuals have only decreased release of ATP from intracytoplasmic granules; the significance of this finding is debated.

TREATMENT OF PATIENTS WITH PLATELET DYSFUNCTION

Successful treatment depends on the severity of both the diagnosis and the hemorrhagic event. In all but severe platelet function defects, desmopressin 0.3 μg/kg IV may be used for mild to moderate bleeding

episodes. In addition to its effect on stimulating levels of VWF and factor VIII, desmopressin corrects bleeding time and augments hemostasis in many individuals with mild to moderate platelet function defects. For individuals with Bernard-Soulier syndrome or Glanzmann thrombasthenia, platelet transfusions of 1 unit/5-10 kg corrects the defect in hemostasis and may be lifesaving. Rarely, antibodies develop to the deficient platelet protein, rendering the patient refractory to the transfused platelets. In such patients, the off-label use of recombinant factor VIIa has been effective, and this treatment is undergoing clinical trials. In both conditions, hematopoietic stem cell transplantation has been curative.

Bibliography is available at Expert Consult.

484.14 Disorders of the Blood Vessels

J. Paul Scott

Disorders of the vessel walls or supporting structures mimic the findings of a bleeding disorder although coagulation studies are usually normal. The findings of petechiae and purpuric lesions in such patients are often attributable to an underlying vasculitis/vasculopathy. Skin biopsy can be particularly helpful in elucidating the type of vascular pathology.

HENOCH-SCHÖNLEIN PURPURA

See Chapter 167.1.

EHLERS-DANLOS SYNDROME

See Chapter 659.

OTHER ACQUIRED DISORDERS

Scurvy, chronic corticosteroid therapy, and severe malnutrition are associated with "weakening" of the collagen matrix that supports the blood vessels. Therefore, these factors are associated with easy bruising, and particularly in the case of scurvy, bleeding gums and loosening of the teeth. Lesions of the skin that initially appear to be petechiae and purpura may be seen in vasculitic syndromes, such as SLE.

Section 8

The Spleen

Chapter 485

Anatomy and Function of the Spleen

Amanda M. Brandow and Bruce M. Camitta

ANATOMY

The splenic precursor is recognizable by 5 wk of gestation. At birth, the spleen weighs approximately 11 g. Thereafter, it enlarges until puberty, reaching an average weight of 135 g, and then diminishes in size during adulthood. Approximately 15% of patients will have an accessory spleen. The major splenic components are a lymphoid compartment *(white pulp)* and a filtering system *(red pulp)*. The white pulp consists of periarterial lymphatic sheaths of T lymphocytes with embedded germinal centers containing B lymphocytes. The red pulp has a skeleton of fixed reticular cells, mobile macrophages, partially collapsed endothelial passages (cords of Billroth), and splenic sinuses. A *marginal zone* rich in dendritic (antigen-presenting) cells separates the red pulp from the white pulp. The splenic capsule contains smooth muscle and contracts in response to epinephrine. Approximately 10% of the blood delivered to the spleen flows rapidly through a closed vascular network. The other 90% flows more slowly through an open system (the *splenic cords*), where it is filtered through 1-5 µm slits before entering the splenic sinuses.

FUNCTION

The unique anatomy and blood flow of the spleen enable it to perform reservoir, filtering, and immunologic functions. The spleen receives 5-6% of the cardiac output, but normally contains only 25 mL of blood. It can retain much more when it enlarges leading to cytopenias. Hematopoiesis is a major splenic function at 3-6 mo of fetal life but then disappears. Splenic hematopoiesis can be resumed in patients with myelofibrosis or severe hemolytic anemia. Factor VIII and one-third of the circulating platelet mass are sequestered in the spleen and can be released by stress or epinephrine injection. Thrombocytosis and leukocytosis occur with loss of the splenic reservoir function. A high platelet count after the loss of splenic function or splenectomy is not associated with an increased risk of thrombosis in children.

Slow blood flow past macrophages and through small openings in the sinus walls facilitates the filtering functions of the spleen. Excess membrane is removed from young red blood cells (RBCs); loss of this function is characterized by target cells, poikilocytosis, and decreased osmotic fragility. The spleen is the primary site for destruction of old RBCs; this function is assumed by other reticuloendothelial cells after splenectomy. The spleen also removes damaged/abnormal red cells (such as spherocytes and antibody-coated RBCs) and damaged/senescent platelets. Intracytoplasmic inclusions may be removed from RBCs without cell lysis. Functional or anatomic hyposplenia is characterized by continued circulation of cells containing nuclear remnants **(Howell-Jolly bodies)**, denatured hemoglobin **(Heinz bodies)**, and other debris in RBCs. This debris may appear as "**pits**" on indirect microscopy.

The spleen plays a large role in host defense against infection. The spleen is the largest lymphoid organ in the body and contains nearly half of the body's total immunoglobulin-producing B lymphocytes. The spleen processes foreign material to stimulate production of opsonizing antibody. Properdin and tuftsin are also produced in the spleen. Thus, young (nonimmune) or hyposplenic individuals are at increased risk for **sepsis** caused by pneumococci and other encapsulated bacteria. The spleen can also use phagocytosis to trap and destroy intracellular parasites. The spleen has a minor role in antibody response to intramuscularly or subcutaneously injected antigens but is required for early antibody production after exposure to intravenous antigens. The spleen may be an important site of antibody production in immune thrombocytopenia purpura.

palpating across the abdomen as the patient inspires deeply or with the patient in the right lateral decubitus position. A splenic edge felt more than 2 cm below the left costal margin is abnormal. An enlarged spleen might descend into the pelvis; when splenomegaly is suspected, the abdominal examination should begin at a lower starting point. Superficial abdominal venous distention may be present when splenomegaly is a result of portal hypertension. Patients may also complain of left upper quadrant pain as the spleen enlarges. Radiologic detection or confirmation of splenic enlargement is done with ultrasonography, CT, or technetium-99 sulfur colloid scan. The latter also assesses splenic function.

DIFFERENTIAL DIAGNOSIS

Table 486-1 lists specific causes of splenomegaly. A thorough history with a focus on systemic complaints (fever, night sweats, malaise, weight loss) and a complete physical exam (with special attention to adenopathy), in combination with a complete blood count and careful review of the peripheral smear can help guide diagnosis.

Pseudosplenomegaly

Abnormally long mesenteric connections may produce a wandering or ptotic spleen. An enlarged left lobe of the liver, a left upper quadrant mass, or a splenic hematoma may be mistaken for splenomegaly.

Splenic cysts may contribute to splenomegaly or mimic it; these may be congenital (epidermoid) or acquired (pseudocyst) after trauma or infarction. Cysts are usually asymptomatic and are found on radiologic evaluation. Splenosis after splenic rupture or an accessory spleen (present in 15% of normal individuals) may also mimic splenomegaly; most are not palpable. The syndrome of congenital polysplenism includes cardiac defects, left-sided organ anomalies, bilobed lungs, biliary atresia, and pseudosplenomegaly (see Chapter 431.11).

Hypersplenism

Increased splenic function (sequestration or destruction of circulating cells) can result in peripheral blood cytopenias (thrombocytopenia, neutropenia, anemia), increased bone marrow activity, and splenomegaly. It is usually secondary to another disease and may be cured by treatment of the underlying condition or, if absolutely necessary, moderated by splenectomy.

Congestive Splenomegaly (Banti Syndrome)

Splenomegaly may result from obstruction in the hepatic, portal, or splenic veins leading to hypersplenism. Wilson disease (see Chapter 357.2), galactosemia (see Chapter 87.2), biliary atresia (see Chapter 356.1), and α_1-antitrypsin deficiency (see Chapter 357) may result in hepatic inflammation, fibrosis, and vascular obstruction. Congenital abnormalities (absence or hypoplasia) of the portal or splenic veins may cause vascular obstruction. Septic omphalitis or thrombophlebitis (spontaneous or as a result of umbilical venous catheterization in neonates) may result in secondary obliteration of these vessels. Splenic venous flow may be obstructed by masses of sickled erythrocytes leading to infarction. When the spleen is the site of vascular obstruction, splenectomy cures hypersplenism. However, since obstruction usually is in the hepatic or portal systems, portacaval shunting may be more helpful, because both portal hypertension and thrombocytopenia contribute to variceal bleeding.

Chapter 487

Hyposplenism, Splenic Trauma, and Splenectomy

Amanda M. Brandow and Bruce M. Camitta

HYPOSPLENISM

Congenital absence of the spleen is associated with complex cyanotic heart defects, dextrocardia, bilateral trilobed lungs, and heterotopic abdominal organs (Ivemark syndrome; see Chapter 431.11). Splenic function is usually normal in children with **congenital polysplenia. Functional hyposplenism** may occur in normal neonates, especially premature infants. Children with sickle cell hemoglobinopathies (see Chapter 462.1) may have splenic hypofunction as early as 6 mo of age. Initially, this is caused by vascular obstruction, which can be reversed with red blood cell (RBC) transfusion or hydroxyurea. The spleen eventually autoinfarcts and becomes fibrotic and permanently nonfunctional. Functional hyposplenism may also occur in malaria (see Chapter 288), after irradiation to the left upper quadrant, and when the reticuloendothelial function of the spleen is overwhelmed (as in severe hemolytic anemia or metabolic storage disease). Splenic hypofunction has been reported occasionally in patients with autoimmune diseases (i.e., rheumatoid arthritis, lupus, sarcoidosis), nephritis, inflammatory bowel disease, celiac disease, chronic hepatitis, Pearson syndrome, Fanconi anemia, and graft-versus-host disease) (Table 487-1).

Table 487-1 Diseases Associated with Hyposplenism or Splenic Atropy

CONGENITAL FORMS Normal and premature neonates Isolated congenital hypoplasia Ivemark syndrome Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome Hypoparathyroidism syndrome Stormorken syndrome Heterotaxia syndromes	**AUTOIMMUNE DISORDERS** Systematic lupus erythematosus Rheumatoid arthritis Glomerulonephritis Wegener granulomatosis Goodpasture syndrome Sjögren syndrome Nodous polyarteritis Thyroiditis Sarcoidosis

From Di Sabatino A, Carsetti R, Corazza GR. Post-splenectomy and hyposplenic states, Lancet 378(9785):86-97, 2011.

Splenic hypofunction is characterized by RBC inclusions in peripheral blood smears (Howell-Jolly bodies or Heinz bodies), **"pits"** on interference microscopy, and poor uptake of technetium or other spleen scans (Table 487-2, Fig. 487-1). Reduced immunoglobulin M memory B cells may also be detected and is a risk factor for overwhelming sepsis. Patients with functional hyposplenism or asplenia are at increased risk for sepsis from encapsulated bacteria and benefit from antibiotic prophylaxis.

SPLENIC TRAUMA

Injury to the spleen may occur with abdominal trauma. Small splenic capsular tears may cause abdominal or referred left shoulder pain as a result of diaphragmatic irritation by blood. Larger tears result in more severe blood loss, with similar pain and signs of hypovolemic shock. Previously enlarged spleens (as in patients with infectious mononucleosis) are more likely to rupture with minor trauma. Patients with splenomegaly should avoid contact sports and other activities that increase the risk of splenic trauma. CT scan with IV contrast is the best imaging modality to assess splenic trauma.

Treatment of a small capsular injury should include careful observation with attention to changes in vital signs or abdominal findings, serial hemoglobin determinations, and the availability of prompt surgical intervention if a patient's condition deteriorates (see Chapter 72).

Table 487-2 Diagnostic Techniques for and Features of Spleen Dysfunction

	DESCRIPTION	COMMENTS
Immunoglobulin M memory B cells	Cells dependent on spleen for survival. Produced in marginal zone	Special tests required
Technetium-99m–labeled sulphur colloidal scintiscan	Quantitation of splenic uptake of colloidal sulphur particles enables a fairly accurate static assessment of spleen function	Hypertrophy of the left hepatic lobe might be a limiting factor (this technique does not clearly show whether the mass originated in the liver or the spleen in the presence of an overlapping hypertropic left hepatic lobe)
Technetium-99m–labeled or rubidium-81–labeled heat-damaged autologous erythrocyte clearance	Measurement of clearance time allows a dynamic evaluation of spleen function	Preexisting erythrocyte defects, difficult erythrocyte incorporation of the radioisotope, false-positive or false-negative results in relation to excessive or insufficient heat damage make the test not suitable for clinical practice
Detection of Howell-Jolly bodies by staining	Erythrocytes with nuclear remnants Flow cytometry	No need for special equipment; inaccurate in the quantitation of splenic hypofunction
Detection of pitted erythrocytes by phase-interference microscopy	Erythrocytes with membrane indentations (4% upper limit of the normal range)	Need for phase-interference microscopy; counts enable a wide range of measurements and correlate with radioisotopic methods

From Di Sabatino A, Carsetti R, Corazza GR. Post-splenectomy and hyposplenic states, Lancet *378(9785):86-97, 2011, Table 1.*

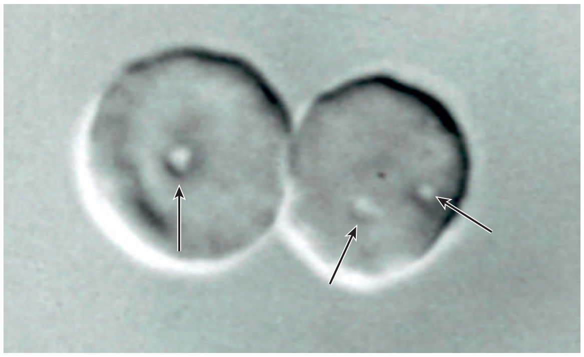

Figure 487-1 **Characteristic pitted erythrocytes.** A pitted erythrocyte is recognizable on phase-interference microscopy by the characteristic "pit" on the cell membrane *(arrows). (From Di Sabatino A, Carsetti R, Corazza GR. Post-splenectomy and hyposplenic states,* Lancet *378[9785]:86-97, 2011, Fig. 2.)*

RBC transfusion requirements should be minimal (<25 mL/kg/48 hr). These patients are usually hospitalized for 10-14 days and have their activities restricted for months. Laparotomy, with or without splenectomy, is indicated for more marked abdominal bleeding, in patients who have clinical instability or deterioration, or when other organ damage is suspected. Partial splenectomy and splenic repair should be substituted for total splenectomy when feasible to maintain some splenic immune function.

SPLENECTOMY

Splenectomy should be limited to specific indications where medical therapy is (or has been) ineffective. These include traumatic splenic rupture, anatomic defects, severe transfusion dependent hemolytic anemia, immune cytopenias, metabolic storage diseases, and secondary hypersplenism. The major long-term risk of splenectomy is sudden, overwhelming postsplenectomy infections (sepsis or meningitis). This risk is especially high in children younger than 5 yr at the time of surgery. The risk of sepsis is less when splenectomy is performed for trauma, RBC membrane defects, and immune thrombocytopenia (2-4%) than when there is sickle cell anemia, thalassemia, or a preexisting immune deficiency (Wiskott-Aldrich syndrome, Hodgkin disease) or reticuloendothelial blockade (storage disease, severe hemolytic anemia) (8-30%). The overall risk is 2-5 per 1,000 asplenic patient years, with a lifelong risk of overwhelming postsplenectomy infections of 5%; more than half occur within 2 yr after splenectomy, although the risk remains lifelong. The use of laparoscopic splenectomy has decreased surgical morbidity and hospitalization time.

Encapsulated bacteria, such as *Streptococcus pneumoniae* (>60% of cases), *Haemophilus influenzae,* and *Neisseria meningitidis,* account for >80% of cases of postsplenectomy sepsis. Because the spleen is responsible for filtering the blood and for early antibody responses, sepsis (with or without meningitis) can progress rapidly, leading to death within 12-24 hr of onset. Febrile splenectomized patients should be evaluated and treated promptly with antibiotics to cover the organisms previously mentioned. This treatment should be initiated at home if access to definitive medical care will be delayed. A broad-spectrum cephalosporin (cefotaxime or ceftriaxone) is recommended until specific antibiotic susceptibility and presence or absence of meningitis is known. Vancomycin (to cover penicillin-resistant pneumococci) should be initiated, depending on the illness severity and susceptibilities of pneumococci at the institution. Splenectomized patients are also at increased risk for contracting protozoal infections, such as malaria and babesiosis. Serious infection may occur after an animal bite (particularly dogs) and is due to *Capnocytophaga canimorsus* or *C. cynodegmi*. Prophylactic antibiotics should be given after a bite to potentially prevent sepsis caused by these organisms (see Chapter 724).

Preoperative, intraoperative, and **postoperative** management may decrease the risk of postsplenectomy infection. It is important to be certain of the need for splenectomy and, if possible, to postpone the operation until the patient is 5 yr of age or older. Pneumococcal, meningococcal, and *H. influenzae* conjugate vaccines given at least 14 days before splenectomy may reduce postsplenectomy sepsis. The 7-valent pneumococcal polysaccharide-protein conjugate vaccine (PCV7) was replaced with the 13-valent pneumococcal polysaccharide-protein conjugate vaccine (PCV13). Thus, depending on what primary pneumococcal vaccine was given, a single dose of PCV13 may be recommended. In addition, the 23-valent pneumococcal polysaccharide vaccine (Pneumovax) should be given at age ≥2 yr and a second dose 5 yr later. Yearly influenza vaccine should also be given as influenza infection is a risk factor for secondary pneumococcal infections. Prophylaxis with oral penicillin VK (125 mg twice daily for children younger than 5 yr; 250 mg twice daily for children 5 yr or older) should be given until at least 5 yr of age and for at least 2 yr after splenectomy. Although the greatest risk is in the immediate postoperative period, reports of deaths occurring years after splenectomy suggest that the risk (and the need for prophylaxis) may be lifelong. Lifelong prophylaxis should be strongly considered in patients who have had an invasive pneumococcal infection or who have an underlying immune deficiency. In children with sickle cell disease, penicillin prophylaxis should be started as soon as the diagnosis is made.

Prophylaxis may be continued into adulthood for higher-risk patients, including those with a history of pneumococcal sepsis, but effectiveness in this older group has not been well documented.

In patients with traumatic injury, splenic repair or partial splenectomy should be considered in an attempt to preserve splenic function. Partial splenectomy or partial splenic embolization may be sufficient to ameliorate some forms of hemolytic anemia. Up to 50% of children whose spleen is removed because of trauma have spontaneous **splenosis**; surgical splenosis (distributing small pieces of spleen throughout the abdomen) may decrease the risk of sepsis in patients whose splenectomy is necessitated by trauma. However, in both of these settings, the splenic tissue that regrows frequently has poor function.

In addition to postsplenectomy sepsis, splenectomized patients may be at risk for **thromboembolic** complications, including arterial and venous thrombosis and **pulmonary hypertension**. These findings have been reported regardless of the underlying reason for splenectomy and the postsplenectomy platelet count. Proposed mechanisms include loss of filtering function of the spleen, allowing abnormal RBCs to remain in the circulation and activate the coagulation cascade. Portal vein thrombosis has been reported as a complication of laparoscopic splenectomy.

Section 9

The Lymphatic System

Chapter 488

Anatomy and Function of the Lymphatic System

Richard L. Tower and Bruce M. Camitta

The lymphatic system participates in many biologic processes, including fluid homeostasis, absorption of dietary fat, and initiation of specific immune responses. This system includes circulating lymphocytes, lymphatic vessels, lymph nodes, spleen, tonsils, adenoids, Peyer patches, and thymus. Lymph, an ultrafiltrate of blood, is collected by lymphatic capillaries that are present in all organs except the brain, bone marrow, retina, cartilage, epidermis, hair, and nails. These join to form progressively larger vessels that drain regions of the body. The lymphatic vessels carry lymph to the lymph nodes, where it is filtered through sinuses, particulate matter and infectious organisms are phagocytosed, and antigens are presented to surrounding lymphocytes. These actions stimulate antibody production, T-cell responses, and cytokine secretion (see Chapter 123). Lymph is ultimately returned to the intravascular circulation.

The composition of lymph can vary with the site of lymph drainage. It is usually clear, but lymph drained from the intestinal tract may be milky (chylous) because of the presence of fats. The protein content is intermediate between that of an exudate and a transudate. The protein level may be increased with inflammation and in lymph drained from the liver or intestines. Lymph also contains variable numbers of lymphocytes and antigen-presenting cells.

Embryonic lymphatic development (primary lymphangiogenesis) proceeds from the stage of lymphatic competence, through lymphatic commitment, specification, coalescence, and maturation. Secondary lymphangiogenesis occurs in the settings of wound healing and inflammation. Many genes are crucial to normal lymphatic development and function, including *Prox1*, vascular endothelial growth factor–C (*VEGF-C*), and vascular endothelial growth factor receptor–3 (*VEGFR-3*).

Chapter 489

Abnormalities of Lymphatic Vessels

Richard L. Tower and Bruce M. Camitta

Abnormalities of the lymph vessels may be congenital or acquired. Signs and symptoms result from increased lymphatic tissue mass or from leakage of lymph. **Lymphangiectasia** is dilation of the lymphatics. Pulmonary lymphangiectasia causes respiratory distress (see Chapter 395.6). Involvement of the intestinal lymphatics causes hypoproteinemia and lymphocytopenia secondary to loss of lymph into the intestines (see Chapter 338). Therapy includes minimizing the hydrostatic pressure in the lymphatic system. Reducing dietary intake of long-chain fatty acids and substituting medium-chain triglycerides may accomplish this goal. If unsuccessful, octreotide or propanolol may be tried. **Lymphangioma** is a congenital lymphatic malformation, usually detected by age 2 yr. **Lymphangioma circumscriptum** is defined as the presence of many small, superficial lymphangiomas. Deeper lymphangiomas are classified as either **cavernous lymphangiomas** or **cystic hygromas**.

Lymphangiomatosis is the presence of multiple or disseminated malformations. Some of these lesions also have a hemangiomatous component (see Chapter 505). Thoracic lymphangiomatosis presents with chylothorax, a mass, or with pulmonary infiltrates. Associated features include bone, skin, and splenic lesions. The disorder is either diffuse or multifocal and is differentiated from lymphangiectasia by the presence of complex anastomosis of vessels with dilation rather than simple dilation of preexisting lymphatic capillaries. Emergent surgical treatment is infrequently necessary due to mass effects. Most lesions may be observed for 18-24 mo to assess for involution. Surgery is effective for superficial lesions, but there is a high incidence of recurrence when used for deeper lesions. Intralesional sclerosing with OK-432, a streptococcal derivative, has been used successfully in selected patients. Other sclerotherapy agents include pure ethanol and bleomycin. Macrocystic lesions appear to respond better than microcystic lymphangiomas to sclerotherapy. Radiofrequency ablation has been used for lymphatic lesions of the tongue. **Lymphatic dysplasia** may cause multisystem problems. These include lymphedema, chylous ascites, chylothorax, and lymphangiomas of the bone, lung, or other sites.

Lymphangioleiomyomatosis is characterized by proliferation of lymphatic endothelial cells and smooth muscle cells in the lungs, leading to airway and lymphatic obstruction, cyst formation, pneumothorax, and respiratory failure. It may initially be mistaken for asthma. Lymphangioleiomyomatosis occurs in young women and is also associated with mutations in the tuberous sclerosis tumor-suppressor gene *TSC2* in one-third of cases. Sirolimus (rapamycin) stabilizes lung function, reduces symptoms, and improves life quality; lung transplantation may be required.

Lymphedema, a localized swelling caused by impaired lymphatic flow, can be congenital or acquired. Congenital lymphedema may be found in Turner syndrome, Noonan syndrome, and the autosomal dominantly inherited Milroy disease, among other chromosomal abnormalities. Several families with Milroy disease have mutations in the vascular endothelial growth factor receptor–3 gene (*VEGFR-3*).

Autosomal recessive and X-linked inheritance has also been reported. Mutations in *GJC2* are associated with hereditary lymphedema. **Lymphedema praecox** (Meige disease) causes progressive lower extremity edema, usually in females during the peripubertal period or pregnancy. **Hypotrichosis-lymphedema-telangiectasia syndrome**, which has dominant and recessive inheritance patterns, has been linked to mutations in *SOX18*. Lymphedema has also been found in association with intestinal lymphangiectasia, cerebrovascular malformation, ptosis, yellow dystrophic nails, distichiasis, and cholestasis. Mutations in *FOXC2* are associated with lymphedema-distichiasis syndrome, which has a pubertal onset of lymphedema. Mutations in *CCBE1*, *PTPN14*, and *GATA2* are associated with Hennekam lymphangiectasia-lymphedema syndrome (lymphedema of the extremities, intestinal lymphangiectasia, mental retardation), lymphedema-choanal atresia syndrome, and Emberger syndrome (lymphedema of the lower extremities and genitalia, deafness, immune dysfunction, and warts), respectively.

Acquired obstruction of the lymphatics can result from tumor, postirradiation fibrosis, and postinflammatory scarring. **Filariasis** is an important cause of lymphedema in Africa, Asia, and Latin America; of the estimated 120 million infected persons, approximately 40 million (primarily older adolescents and adults) are believed to have lymphedema or hydrocele. Injury to the major lymphatic vessels can cause collection of lymph fluid in the abdomen (chylous ascites) or chest (chylothorax). Untreated lymphedema can be disabling and is associated with immune dysfunction, inflammation, fibrosis, adipose tissue overgrowth, and **lymphangiosarcoma**. Current treatment modalities attempt to reduce localized swelling through massage, exercise, and compression. No drugs have been proven efficacious. Diuretic use should be avoided. The recently discovered gene mutations provide potential for targeted therapy, including gene therapy. Autologous lymph node transplantation and use of growth factors to stimulate lymphangiogenesis may also be on the horizon for treatment of lymphedema.

Lymphangitis is an inflammation of the lymphatics that drain an area of infection. Tender, erythematous streaks extend proximally from the infected area. Regional nodes may also be tender. Group A streptococci and *Staphylococcus aureus* are the most frequent pathogens and therapy should include antibiotics that treat these organisms.

Chapter **490**

Lymphadenopathy

Richard L. Tower and Bruce M. Camitta

Palpable lymph nodes are common in pediatrics. Lymph node enlargement is caused by proliferation of normal lymphoid elements or by infiltration with malignant or phagocytic cells. In most patients, a careful history and a complete physical examination suggest the proper diagnosis.

DIAGNOSIS

Is the mass a lymph node? Nonlymphoid masses (cervical rib, thyroglossal cyst, branchial cleft cyst or infected sinus, cystic hygroma, goiter, sternomastoid muscle tumor, thyroiditis, thyroid abscess, neurofibroma) occur frequently in the neck and less often in other areas. **Is the node enlarged?** Lymph nodes are not usually palpable in the newborn. With antigenic exposure, lymphoid tissue increases in volume. They are not considered enlarged until their diameter exceeds 1 cm for cervical and axillary nodes and 1.5 cm for inguinal nodes. Other lymph nodes usually are not palpable or visualized with plain radiographs. **What are the characteristics of the node?** Acutely infected nodes are usually tender. There may also be erythema and warmth of the overlying skin. Fluctuance suggests abscess formation. Tuberculous nodes may be matted. With chronic infection, many of these signs are not present. Tumor-bearing nodes are usually firm and nontender and may be matted or fixed to the skin or underlying structures.

Is the lymphadenopathy localized or generalized? Generalized adenopathy (enlargement of >2 noncontiguous node regions) is caused by systemic disease (Table 490-1) and is often accompanied by abnormal physical findings in other systems. In contrast, regional adenopathy is most frequently the result of infection in the involved node and/or its drainage area (Table 490-2). When caused by infectious agents other than bacteria, adenopathy may be characterized by atypical anatomic areas, a prolonged course, a draining sinus, lack of prior pyogenic infection, and unusual clues in the history (cat scratches, tuberculosis exposure, venereal disease). A firm, fixed node should always raise the question of malignancy, regardless of the presence or absence of systemic symptoms or other abnormal physical findings.

TREATMENT

Evaluation and treatment of lymphadenopathy is guided by the probable etiologic factor, as determined from the history and physical examination. Many patients with cervical adenopathy have a history compatible with viral infection and need no intervention. If bacterial infection is suspected, antibiotic treatment covering at least streptococci and staphylococci is indicated. Those who do not respond to oral antibiotics, as demonstrated by persistent swelling and fever, require IV antistaphylococcal antibiotics. If there is no response in 1-2 days, or if there are signs of airway obstruction or significant toxicity, ultrasound, CT, or MRI of the neck should be obtained. If pus is present, it may be aspirated, with CT or ultrasound guidance, or if it is extensive, may require incision and drainage. Gram stain and culture of the pus should be obtained. The sizes of involved nodes should be documented before treatment. Failure to decrease in size within 10-14 days also suggests the need for further evaluation. This may include a complete blood cell

Table 490-2 Sites of Local Lymphadenopathy and Associated Diseases

CERVICAL
Oropharyngeal infection (viral or group A streptococcal, staphylococcal)
Scalp infection/infestation (head lice)
Mycobacterial lymphadenitis (tuberculosis and nontuberculous mycobacteria)
Viral infection (EBV, CMV, HHV-6)
Cat-scratch disease
Toxoplasmosis
Kawasaki disease
Thyroid disease
Kikuchi disease
Sinus histiocytosis (Rosai-Dorfman disease)
Autoimmune lymphoproliferative disease
Periodic fever, aphthous stomatitis, pharyngitis, cervical adenopathy (PFAPA) syndrome
ANTERIOR AURICULAR
Conjunctivitis
Other eye infection
Oculoglandular tularemia
Facial cellulitis
Otitis media

count with differential; Epstein-Barr virus, cytomegalovirus, *Toxoplasma,* and cat-scratch disease titers; antistreptolysin O or anti-DNAse serologic tests; tuberculin skin test; and chest radiograph. If these are not diagnostic, consultation with an infectious disease or oncology specialist may be helpful. Biopsy should be considered if there is persistent or unexplained fever, weight loss, night sweats, supraclavicular location, mediastinal mass, hard nodes, or fixation of the nodes to surrounding tissues. Biopsy may also be indicated if there is an increase in size over baseline in 2 wk, no decrease in size in 4-6 wk, no regression to "normal" in 8-12 wk, or if new signs and symptoms develop.

Differentiating benign disorders from a malignancy may initially be difficult. Hard, nontender, nonerythematous nodes involving multiple regions (including mediastinum and abdomen), hepatic or splenic enlargement, fever, night sweats, and weight loss suggest malignancy or a granulomatous process. Persistence of symptoms and lymphadenopathy greater than 2 wk and certain locations (supraclavicular, mediastinal, abdomen) also suggest malignancy. Cytopenias and elevated blood lactate dehydrogenase are associated with malignancy and certain inflammatory disorders. CT imaging is helpful in identifying other affected nodes and organs; CT or ultrasonographic guided biopsy is helpful in determining the etiology. Fine needle aspiration or excisional biopsy may be needed for superficial nodes to determine a diagnosis.

490.1 Kikuchi-Fujimoto Disease (Histiocytic Necrotizing Lymphadenitis)

Richard L. Tower and Bruce M. Camitta

Kikuchi-Fujimoto disease is a rare, usually self-limiting disease that was originally reported in patients of Asian heritage. Cases are now described in all ethnic groups. Familial cases have been reported. Presentation is varied and may include fever of unknown origin, but more often, it occurs in children 8-16 yr of age as firm unilateral posterior cervical adenitis, fever, malaise, elevated erythrocyte sedimentation rate, atypical lymphocytosis, and leukopenia. Nodes range in size from only 0.5-6.0 cm, are painful or tender in only 50% of cases, may be multiple, and must be differentiated from lymphoma. Node involvement may occasionally be bilateral or present in axillary or supraclavicular nodes.

The etiology is unknown, although viral and bacterial causes have been suggested. Growing evidence supports an abnormal immune response; the diagnosis is made by lymph node biopsy. Histologic features include necrosis with karyorrhexis, a histiocytic infiltrate, crescentic plasmacytoid monocytes and an absence of neutrophils. The disease is self-limiting and usually spontaneously resolves within 6 mo, although relapses have occurred up to 16 yr later. Therapy with systemic steroids is reserved for cases with severe symptoms. Rarely, the disease has been fatal. Many autoimmune diseases have been associated with Kikuchi-Fujimoto disease, most commonly systemic lupus erythematosus. The differential diagnosis includes lymphoma, tuberculosis, and systemic lupus erythematosus.

490.2 Sinus Histiocytosis with Massive Lymphadenopathy (Rosai-Dorfman Disease)

Richard L. Tower and Bruce M. Camitta

This uncommon, benign, and usually self-limited disease has a worldwide distribution but is more common in Africa and the Caribbean. The etiology is unknown, but immune dysfunction is suspected. Patients present with massive bilateral, painless, mobile cervical adenopathy, along with fever, leukocytosis, high erythrocyte sedimentation

rate, and polyclonal elevation of immunoglobulin G (hypergammaglobulinemia). Night sweats and weight loss are common. Autoimmune hemolytic anemia is an uncommon associated finding. It rarely occurs at birth or in siblings, and males are affected more often than females.

Other nodal chains may be involved. Extranodal involvement occurs in 40% of cases. Soft-tissue involvement of all organ systems has been reported. The most common sites are the skin, followed by the nasal cavity and sinuses, palate, orbit, bone, and central nervous system. Occasionally autoantibodies to erythrocytes or synovium may be present. A biopsy that demonstrates pale histiocytes containing engulfed lymphocytes (**emperipolesis**), and immunoreactivity to S100 protein in large histiocytes, in conjunction with expected clinical features, is diagnostic. The differential diagnosis includes Langerhans cell histiocytosis, myeloproliferative disorders, and lymphoma.

Therapy is usually not needed for this self-limited disease. However, the disease may recur frequently for many years. Life- or organ-threatening disease or exacerbations may respond to prednisone. Refractory cases have been treated with surgical excision or radiation. Rare patients have been treated with immune-modulating therapy, including interferon-α, 2-chlorodeoxyadenosine, imatinib, and rituximab. Therapy with antibiotics and chemotherapy has been unsuccessful.

Bibliography is available at Expert Consult.

490.3 Castleman Disease

Richard L. Tower and Bruce M. Camitta

Castleman disease is an uncommon lymphoproliferative disease and is also called *angiofollicular lymph node hyperplasia*. The underlying etiology is unknown, although an association with human herpesvirus 8 has been identified. Human herpesvirus 8 may stimulate excessive production of interleukin 6 (IL-6). The disease usually presents in adolescents or young adults. Enlargement of a single node, most often in the mediastinum or abdomen, is the most common localized presentation. Some patients may have fever, night sweats, weight loss, and fatigue. Management includes surgery and/or radiation therapy.

Multicentric Castleman disease is a systemic lymphoproliferative disorder that causes lymphadenopathy, hepatosplenomegaly, fever, anemia, overexpression of IL-6, and polyclonal hypergammaglobulinemia. Multicentric Castleman disease may be associated with HIV infection, autoimmune disease–associated lymphadenopathy, and POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M-proteins, and skin lesions). Non-Hodgkin lymphoma may be concurrent or may develop as a result of disease progression. There is no standard treatment for multicentric Castleman disease. Therapeutic options include chemotherapy, steroids, monoclonal antibodies to CD20 (rituximab), monoclonal antibodies (siltuximab) to IL-6, anti-IL-6–receptor antibodies (tocilizumab), antiviral agents, and interferon-α. Chemotherapy regimens used for diffuse large B-cell lymphoma and/or rituximab is currently the most common frontline therapies and has achieved durable remissions. Ganciclovir is the most active antiviral agent. Steroids and anti-IL-6 therapies provide symptomatic relief, but symptoms return after stopping therapy.

Cancer and Benign Tumors

PART XXII

Chapter 491

Epidemiology of Childhood and Adolescent Cancer

Barbara L. Asselin

Cancer in patients younger than 20 yr of age is uncommon, with an age-adjusted annual incidence of 18.7 per 100,000 children ages 0-19 yr, representing only approximately 1% of all new cancer cases in a year in the United States or an estimated 16,600 new cases/yr in 2014. This translates to nearly a 1 in 300 chance of developing cancer by age 20 yr. Although the relative 5 yr survival rates have improved from 61% in 1977 to 83.6% in 2010 in all age groups 0-19 yr (Fig. 491-1), malignant neoplasms remain the leading cause of disease-related (noninjury) mortality (12%) among persons 1-19 yr of age with 1,800-1,900 cancer-related deaths annually in the United States among children and adolescents 0-19 yr of age. The relative contribution of cancer to the overall mortality in infants 0-1 yr old and adolescents 15-19 yr old is lower than for children ages 1-14 yr. The impressive improvements in survival over the past 3.5 decades are attributed primarily to advances in treatment and enrollment in clinical trials for the majority of patients. Multiinstitutional cooperative clinical trials investigating novel therapies and investigating ways to improve survival rates even further and to decrease treatment-related long-term complications are ongoing. Because increasingly more patients survive their disease, clinical investigations also are focusing on the quality of life among survivors and the late outcomes of therapy for pediatric and adult survivors of childhood cancer. The National Cancer Institute estimates that in 2010 there were 380,000 persons alive (in all age groups) who had survived childhood cancer, corresponding to 1 in 810 of persons younger than 20 yr of age and 1 in 1,000 persons 20-39 yr of age in the U.S. population.

Pediatric malignancies differ markedly from adult malignancies in both prognosis and distribution by histology and tumor site. Lymphohematopoietic cancers (i.e., acute lymphoblastic leukemia, myeloid leukemia, Hodgkin and non-Hodgkin lymphomas) account for approximately 40%, central nervous system cancers for approximately 30%, and embryonal tumors and sarcomas for approximately 10% among the broad categories of childhood cancers (Table 491-1). In contrast, epithelial tumors of organs such as lung, colon, breast, and prostate, which are commonly seen among adults, are rare malignancies in children. Incidence patterns in the pediatric age group show 2 peaks: the first in early childhood and the second in adolescence (Fig. 491-2). During the 1st yr of life, *embryonal tumors* such as neuroblastoma, nephroblastoma (Wilms tumor), retinoblastoma, rhabdomyosarcoma, hepatoblastoma, and medulloblastoma are most common (Figs. 491-3 and 491-4). These tumors are much less common in older children and adults after cell differentiation processes have slowed considerably. Embryonal tumors, acute leukemias, non-Hodgkin lymphomas, and gliomas peak in incidence from 2-5 yr of age. As children age, bone malignancies, Hodgkin disease, gonadal germ cell malignancies (testicular and ovarian carcinomas), and other carcinomas increase in incidence. Adolescence is a transitional period between the common early childhood malignancies and characteristic carcinomas of adulthood (Fig. 491-4). Incidence rates also vary by gender (generally higher in boys vs girls), race/ethnicity (more common in whites), and between countries (data assembled by the International Agency for Research in Cancer in Lyon, France, http://www.iarc.fr/). Over the past 35 yr, 1975-2010, there has been some increase in the incidence of children and adolescents diagnosed with cancer particularly in occurrence of leukemia and among adolescents. These variations are not fully understood but likely reflect differences in genetic susceptibility and environmental exposures related to both known and unknown causes and risk factors for cancer (Table 491-2).

Childhood cancer includes a diverse array of malignant tumors, termed "cancers," and nonmalignant tumors arising from disorders of genetic processes involved in control of cellular growth and development. Although many genetic conditions are associated with increased risks for childhood cancer, such conditions are believed to account for <5% of all occurrences (see Chapter 492). The most notable genetic conditions that impart susceptibility to childhood cancer are neurofibromatosis types 1 and 2, Down syndrome, Beckwith-Wiedemann syndrome, tuberous sclerosis, von Hippel-Lindau disease, xeroderma pigmentosum, ataxia-telangiectasia, nevus basal cell carcinoma syndrome, and Li-Fraumeni (*P53*) syndrome. The varying incidence patterns of individual childhood cancers around the world imply additional genetic and epidemiologic risk factors that remain uncharacterized.

Compared with adult epithelial tumors, an extremely small fraction of pediatric cancers appear to be explained by known environmental exposures (see Table 491-2). Ionizing radiation exposure and several chemotherapeutic agents explain only a small number of pediatric cases (see Chapter 718). The association between fetal exposures and pediatric cancer is largely not established, with the exception of maternal diethylstilbestrol intake during pregnancy and subsequent vaginal adenocarcinoma in adolescent daughters. Environmental exposures that have been studied without convincing evidence for a causal role include nonionizing power frequency electromagnetic fields, pesticides, parental occupational chemical exposures, dietary factors, in vitro fertilization, and environmental cigarette smoke. Viruses have been associated with certain pediatric cancers, such as polyomaviruses (BK, JC, SV40) associated with brain cancer and Epstein-Barr virus with non-Hodgkin lymphoma, but the etiologic importance remains unclear. The etiology of cancer in children still is poorly understood, and epidemiology studies demonstrate that the likely mechanisms are multifactorial, possibly resulting from potential interactions between genetic susceptibility traits and environmental exposures. Ongoing studies are investigating the role of polymorphisms of genes encoding enzymes, which function in the activation or metabolism of xenobiotics, protection of cells against oxidative stress, DNA repair, and/or immune modulation.

Curative therapy with chemotherapy, radiation, and/or surgery can adversely affect a child's development and result in serious long-term medical and psychosocial effects in childhood and adulthood. Potential adverse late effects include subsequent second malignancy, early mortality, infertility, reduced stature, cardiomyopathy, pulmonary fibrosis, osteoporosis, neurocognitive impairment, affective disorders, and altered social functioning. Much has been learned about the incidence of late effects from large multisite cohort studies such as the Childhood Cancer Survivor Study, an ongoing study of medical and psychosocial outcomes in survivors, which has provided data for the development of clinical care guidelines for survivors (http://www.survivorshipguidelines.org).

Given the relative rarity of specific types of childhood cancer and the sophisticated technology and expertise required for diagnosis, treatment, and monitoring of late effects, all children with cancer

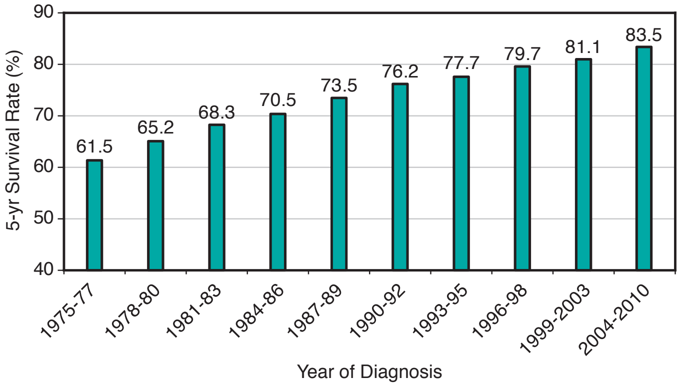

Figure 491-1 **Five yr relative survival rates (%) by year of diagnosis of all cancers in children 19 yr of age or younger.** The difference between the periods 1975-1977 and 2004-2010 is statistically significant ($p < 0.05$). Rates based on follow-up of patients into 2011 from Surveillance, Epidemiology, and End Results (SEER) database. *(Data compiled from Howlader N, Noone AM, Krapcho M, et al, editors: SEER Cancer Statistics Review, 1975-2011, Section 28. Germ cell tumors	19	4	3	8	31	92
Malignant epithelial cancer	—	1.8	4	14	50	92 (99.5*/95†)

Based on the International Classification of Childhood Cancer (ICCC). Rates are per 1,000,000 children and are age-adjusted to the 2000 U.S. standard population.

*Thyroid carcinoma.

†Malignant melanoma.

—, Indicates that the rate could not be calculated with <16 cases for the time interval; ALL, acute lymphoid leukemia; AML, acute myeloid leukemia; CNS, central nervous system.

Data compiled From Howlader N, Noone AM, Krapcho M, et al, editors: SEER Cancer Statistics Review, 1975-2011, Section 29. Bethesda, MD, National Cancer Institute. Available at http://seer.cancer.gov/csr/1975_2011/, posted to the SEER website, April 2014.

Table 491-2 Known Risk Factors for Selected Childhood Cancers

CANCER TYPE	RISK FACTOR	COMMENTS
Acute lymphoid leukemia	Ionizing radiation	Although primarily of historical significance, prenatal diagnostic x-ray exposure increases risk. Therapeutic irradiation for cancer treatment also increases risk.
	Race	White children have a 2-fold higher rate than black children in the United States.
	Genetic factors*	Down syndrome is associated with an estimated 10-20–fold increased risk. NF1, Bloom syndrome, ataxia-telangiectasia, and Langerhans cell histiocytosis, among others, are associated with an elevated risk.
Acute myeloid leukemias	Chemotherapeutic agents	Alkylating agents and epipodophyllotoxins increase risk.
	Genetic factors*	Down syndrome and NF1 are strongly associated. Familial monosomy 7 and several other genetic syndromes are also associated with increased risk.
Brain cancers	Therapeutic ionizing radiation to the head	With the exception of cancer radiation therapy, higher risk from radiation treatment is essentially of historical importance.
	Genetic factors*	NF1 is strongly associated with optic gliomas, and, to a lesser extent, with other central nervous system tumors. Tuberous sclerosis and several other genetic syndromes are associated with increased risk.
Hodgkin disease	Family history	Monozygotic twins and siblings are at increased risk.
	Infections	EBV is associated with increased risk.
Non-Hodgkin lymphoma	Immunodeficiency	Acquired and congenital immunodeficiency disorders and immunosuppressive therapy increase risk.
	Infections	EBV is associated with Burkitt lymphoma in Africa.
Osteosarcoma	Ionizing radiation	Cancer radiation therapy and high radium exposure increase risk.
	Chemotherapy	Alkylating agents increase risk.
	Genetic factors*	Increased risk is apparent with Li-Fraumeni syndrome and hereditary retinoblastoma.
Ewing sarcoma	Race	White children have about a 9-fold higher incidence rate than black children in the United States.
Neuroblastoma		Neurocristopathies.
Retinoblastoma	Genetic factors*	No established other risk factors.
Wilms tumor	Congenital anomalies	Aniridia, Beckwith-Wiedemann syndrome, and other congenital and genetic conditions are associated with increased risk.
	Race	Asian children reportedly have about half the rates of white and black children.
Renal medullary carcinoma	Sickle cell trait	Etiology unknown.
Rhabdomyosarcoma	Congenital anomalies and genetic conditions	Li-Fraumeni syndrome and NF1 are believed to be associated with increased risk. There is some concordance with major birth defects.
Hepatoblastoma	Genetic factors*	Beckwith-Wiedemann syndrome, hemihypertrophy, Gardner syndrome, and family history of adenomatous polyposis are associated with increased risk.
Leiomyosarcoma	Immunosuppression and EBV infection	EBV is associated with leiomyosarcoma for all forms of congenital and acquired immunosuppression but not leiomyosarcoma among immunocompetent persons.
Malignant germ cell tumors	Cryptorchidism	Cryptorchidism is a risk factor for testicular germ cell tumors.

should be treated with standardized clinical protocols in pediatric clinical research settings whenever possible. Promoting such treatment, the Children's Oncology Group is a multiinstitutional research consortium that facilitates cooperative clinical, biologic, and epidemiologic research in more than 200 affiliated institutions in the United States, Canada, and other countries (http://childrensoncologygroup.org/). Coordinated participation in such research trials has been a major factor in the increased survival for many children with cancer. Such ongoing efforts are critical to better understand the etiology of childhood cancers, improve survival for malignancies with a poor prognosis, and maximize the quality of life for survivors.

INFLUENCING THE INCIDENCE OF CANCER

Pediatricians have a unique opportunity to educate children and adolescents, and their parents, regarding means of preventing cancer. There are only a few recognized environmental causes of childhood cancer that can be avoided or counteracted. One example is immunization against hepatitis B, which does decrease the risk of hepatocellular carcinoma in adolescence and adulthood; another is human papillomavirus vaccination, which prevents cervical cancer. Associations between cumulative radiation exposure from common diagnostic radiologic tests such as CT scans and an increased risk of malignancy later in life are of great concern for pediatricians. Guidelines to ensure the safe clinical use of diagnostic imaging are being evaluated (http://www.imagegently.org/). An objective of pediatric medicine is to teach children how to adopt healthy lifestyles to reduce their risk of cancer during adulthood, such as avoiding tobacco, alcohol, high-fat diets, and obesity. The earlier these habits are instilled, the greater the lifelong benefit and the more likely it is to be present and sustained during adulthood.

Chapter **492**

Molecular and Cellular Biology of Cancer

Laura L. Worth

Cancer is a complex of diseases arising from alterations that can occur in a wide variety of genes. Alterations in normal cellular processes such as signal transduction, cell-cycle control, DNA repair, cellular growth and differentiation, translational regulation, senescence, and apoptosis (programmed cell death) can result in a malignant phenotype.

GENES INVOLVED IN ONCOGENESIS

Two major classes of genes are implicated in the development of cancer: oncogenes and tumor-suppressor genes. **Protooncogenes** are cellular genes that are important for normal cellular function and code for various proteins, including transcriptional factors, growth factors, and growth factor receptors. These proteins are vital components in the network of signal transduction that regulate cell growth, division, and differentiation. Protooncogenes can be altered to form **oncogenes**—genes that, when translated, can result in the malignant transformation of a cell.

Oncogenes can be divided into 5 different classes based on their mechanisms of action. Changes in any of these normal cellular components can result in unchecked cell growth. Some oncogenes code for **growth factors** that bind to a receptor and stimulate the production of a protein. Other oncogenes code for **growth factor receptors.** These are proteins on the cell surface. When growth factors bind to a growth factor receptor, they can turn the receptor on or off. Mutational or posttranslational modifications of the receptor can result in a receptor being permanently turned on with consequent unregulated growth. **Signal transducers** or effectors make up another class. Signal transducers are responsible for taking the signal from the cell surface receptor to the cell nucleus. *NRAS*, as described below, is an example of this class of protein. **Transcription factors** are molecules that bind to specific areas of the DNA and control transcription. *MYC,* described below, is an example of a transcription factor that results in overstimulation of cell division. The final class of oncogenes interferes with apoptosis. Cells that no longer respond to the signal to die can continue to proliferate.

The 3 main mechanisms by which protooncogenes can be activated include amplification, point mutations, and translocation (Table 492-1). *MYC,* which codes for a protein that regulates transcription, is an example of a protooncogene that is activated by amplification. Patients with neuroblastoma in which the *MYC* gene is amplified 10-300–fold have a poorer outcome. Point mutations can also activate protooncogenes. The *NRAS* protooncogene codes for a guanine nucleotide–binding protein with guanosine triphosphatase activity that is important in signal transduction and is mutated in 25-30% of acute nonmyelogenous leukemias, resulting in a constitutively active protein. The RET protein is a transmembrane tyrosine kinase receptor that is important in signal transduction. A point mutation in the *RET* gene results in the constitutive activation of a tyrosine kinase, as found in multiple neoplasia syndromes and familial thyroid carcinoma.

The third mechanism by which protooncogenes become activated is by chromosomal translocation. In some leukemias and lymphomas, transcription factor controlling sequences are relocated in front of T-cell receptors or immunoglobulin genes, resulting in unregulated transcription of the genes and leukemogenesis. Chromosomal translocations can also result in **fusion genes**; transcription of the fusion gene can result in the production of a chimeric protein with new and potentially oncogenic activity. Examples of cancers associated with fusion genes include the childhood solid tumors like Ewing sarcoma [t(11;22)] and alveolar rhabdomyosarcoma [t(2;13) or t(1;13)]. The translocations result in novel proteins that are useful as diagnostic markers. The best-described translocation in leukemia is the **Philadelphia chromosome's t(9;22)**, which results in the BCR/ABL protein found in chronic myelogenous leukemia. This translocation results in a tyrosine kinase protein that is constitutively activated. In addition, the protein is localized to the cytoplasm instead of the nucleus, exposing the kinase to a new spectrum of substrates.

Alteration in the regulation of tumor-suppressor genes is another mechanism involved in oncogenesis. Tumor-suppressor genes are important regulators of cellular growth and apoptosis. They have been called recessive oncogenes because the inactivation of both alleles of a tumor-suppressor gene is required for expression of a malignant phenotype.

Knudson's **"2-hit" model of cancer development** was based on the observation of the behavior of the *RB* tumor-suppressor gene. In sporadic cases of retinoblastoma, both alleles of the *RB* gene must be inactivated. However, in familial cases, children inherit an inactivated allele from 1 parent and consequently require the inactivation of the only remaining normal allele. This helps explain why familial cases of retinoblastoma occur earlier in childhood than sporadic cases, because only 1 "hit" is required.

Another major tumor-suppressor protein is P53, which is known as the "guardian of the genome" because it detects the presence of

Table 492-1 Oncogene Activators of Pediatric Tumors

MECHANISM	CHROMOSOME	GENES	PROTEIN FUNCTION	TUMOR
Chromosomal translocation	t(9;22)	*BCR-ABL*	Chimeric tyrosine kinase	CML, ALL
	t(1:19)	*E2A-PBX1*	Chimeric transcription factor	Pre-B ALL
	t(14:18)	*CMYC*	Transcription factor	Burkitt lymphoma
	t(15;17)	*APL-RARα*	Chimeric transcription factor	APL
	11:q23 and others	*MLL*	Methyl transferase activity	ALL AML Biphenotypic
	t(12;q21)	*TEL-AML 1*	Chimeric protein	ALL
	t(2;13)(q35;q14) or t(1,13)(p36q14)	*FKHF-PAX3*	Transcription factor	Rhabdomyosarcoma
	t(11;q22) or t(7;q22)	*EWS-FLI1*	Transcription factor	Wilms
Gene amplification	Amplicon	*NMYC*	Transcription factor	Neuroblastoma
	Amplicon	*EGFR*	Growth factor kinase, tyrosine kinase	Glioblastoma
	Amplicon	*Flt3*	Tyrosine kinase receptor	AML
Point mutation	1p	*NRAS*	Guanosine triphosphatase	AML
	10q	*RET*	Tyrosine kinase	MEN2

ALL, acute lymphocytic leukemia; AML, acute myelocytic leukemia; APL, acute promyelocytic leukemia; CML, chronic myelogenous leukemia; MEN2, multiple endocrine neoplasia, type 2.

chromosomal damage and prevents the cell from dividing until repairs have been made. In the presence of damage beyond repair, P53 initiates apoptosis and the cell dies. More than 50% of all tumors have abnormal P53 proteins. Mutations in the *P53* gene are important in many cancers, including breast, colorectal, lung, esophageal, stomach, ovarian, and prostatic carcinomas as well as gliomas, sarcomas, and some leukemias.

PTEN (phosphatase and tensin homolog) is one of the most commonly lost tumor suppressors in human cancer. PTEN is a phosphatase that regulates cell-cycle progression. The dephosphorylation of proteins disrupts the Akt/PKB signaling pathway that moderates cell-cycle progression. Loss of PTEN enzyme activity is seen in Proteus, Cowden, and Bannayan-Riley-Ruvalcaba syndromes and in glioblastoma, endometrial carcinoma, and prostate cancer. Decreased phosphatase activity is found in lung and breast cancer. More than 170 putative tumor-suppressor genes are identified.

SYNDROMES PREDISPOSING TO CANCER

Several syndromes are associated with an increased risk of developing malignancies, which can be characterized by different mechanisms (Table 492-2). One mechanism involves the inactivation of tumor-suppressor genes such as *RB* in **familial retinoblastoma**. Interestingly, patients with retinoblastoma in which 1 of the alleles is inactivated throughout all of the patient's cells are also at a very high risk for developing osteosarcoma. A familial syndrome, **Li-Fraumeni syndrome**, in which 1 mutant *P53* allele is inherited, also has been described in patients who develop sarcomas, leukemias, and cancers of the breast, bone, lung, and brain. **Neurofibromatosis** is a condition characterized by the proliferation of cells of neural crest origin, leading to neurofibromas. These patients are at a higher risk of developing malignant schwannomas and pheochromocytomas. Neurofibromatosis is often inherited in an autosomal dominant fashion, although 50% of the cases present without a family history and occur secondary to the high rate of spontaneous mutations of the *NF1* gene.

A second mechanism responsible for an inherited predisposition to develop cancer involves defects in DNA repair. Syndromes associated with an excessive number of broken chromosomes due to repair defects include **Bloom syndrome** (short stature, photosensitive telangiectatic erythema), ataxia-telangiectasia (childhood ataxia with progressive neuromotor degeneration), and **Fanconi anemia** (short stature, skeletal and renal anomalies, pancytopenia). As a result of the decreased ability to repair chromosomal defects, cells accumulate abnormal DNA that results in significantly increased rates of cancer, especially leukemia. **Xeroderma pigmentosum** likewise increases the risk of skin cancer, owing to defects in repair to DNA damaged by ultraviolet light. These disorders display an autosomal recessive pattern.

Table 492-2 Familial or Genetic Susceptibility to Malignancy

DISORDER	TUMOR/CANCER	COMMENT
CHROMOSOMAL SYNDROMES		
Chromosome 11p deletion syndrome with sporadic aniridia	Wilms tumor	Associated with genitourinary anomalies, mental retardation, *WT1* gene
Chromosome 13q deletion syndrome	Retinoblastoma, sarcoma	Associated with intellectual disability, skeletal malformations; autosomal dominant (bilateral) or sporadic new mutations, *RB1* gene
Trisomy 21	Lymphocytic or nonlymphocytic leukemia, especially megakaryocytic leukemia; transient leukemoid reaction	Risk of ALL is increased 20%; risk of AML is increased 400%; patients have an increased sensitivity to chemotherapy
Klinefelter syndrome (47,XXY)	Breast cancer, extragonadal germ cell tumors	
Trisomy 8	Preleukemia	
Noonan syndrome	JMML	Autosomal dominant; mutations in *PTPN11* gene
Monosomy 5 or 7	Myelodysplastic syndrome	Recurrent infections may precede neoplasia
CHROMOSOMAL INSTABILITY		
Xeroderma pigmentosum	Basal cell and squamous cell carcinomas; melanoma	Autosomal recessive; failure to repair UV-damaged DNA. Mutations in *XP* gene on chromosome 3p25
Fanconi anemia	Leukemia, myelodysplastic syndrome, liver neoplasias, rare head and neck tumors, GI and GU cancers	Autosomal recessive; chromosome fragility; positive diepoxybutane test result. Mutations in *FANCX* gene family
Bloom syndrome	Leukemia, lymphoma, and solid tumors	Autosomal recessive; increase sister chromatid exchange; mutations in *BLM* gene; member of the RecQ helicase gene
Ataxia-telangiectasia	Lymphoma, leukemia, less commonly central nervous system and nonneural solid tumors	Autosomal recessive; sensitive to X-irradiation, radiomimetic drugs; mutation in *ATM* tumor-suppressor gene
Dysplastic nevus syndrome	Melanoma	Autosomal dominant; some cases associated with mutations in *CDKN2A* gene
Rothmund-Thompson syndrome	Osteosarcoma; skin cancers	Autosomal recessive; mutation in RecQ helicase gene family
Werner syndrome (premature aging)	Soft tissue sarcomas	Autosomal recessive; mutation in the *WRN* gene; member of the RecQ helicase gene family
IMMUNODEFICIENCY SYNDROMES		
Wiskott-Aldrich syndrome	Lymphoma, leukemia	X-linked recessive; *WAS* gene mutation (Xp11.22-23); WASP protein functions in signal transduction associated with cytoskeletal actin filament rearrangement
X-linked immunodeficiency (Duncan syndrome)	Lymphoproliferative disorder	X-linked; Epstein-Barr viral infection can result in fatal outcome; mutation in *SH2D1A* gene locus
X-linked agammaglobulinemia (Bruton disease)	Lymphoma, leukemia	X-linked; mutation in *BKT* gene resulting in absence of mature B cells
Severe combined immunodeficiency	Leukemia, lymphoma	X-linked; mutations in *ADA* gene

Table 492-2 Familial or Genetic Susceptibility to Malignancy—cont'd

DISORDER	TUMOR/CANCER	COMMENT
OTHERS		
Neurofibromatosis 1	Neurofibroma, optic glioma, acoustic neuroma, astrocytoma, meningioma, pheochromocytoma, sarcoma	Autosomal dominant; mutation in tumor-suppressor gene, *NF1*
Neurofibromatosis 2	Bilateral acoustic neuromas, meningiomas	Autosomal dominant; mutation in tumor-suppressor gene, *NF2*
Tuberous sclerosis	Fibroangiomatous nevi, myocardial rhabdomyoma	Autosomal dominant
Gorlin-Goltz syndrome (nevus basal cell carcinoma syndrome)	Multiple basal cell carcinomas; medulloblastoma	Autosomal dominant; mutation in *PTCH* gene
Li-Fraumeni syndrome	Bone, soft tissue sarcoma, breast	Mutation of *P53* tumor-suppressor gene, autosomal dominant
Retinoblastoma	Sarcoma	Autosomal recessive; increased risk of secondary malignancy 10-20 yr later; mutation in *RB* tumor-suppressor gene
Hemihypertrophy ± Beckwith syndrome	Wilms tumor, hepatoblastoma, adrenal carcinoma	*WT1* gene; 25% develop tumor, most in 1st 5 yr of life
von Hippel-Landau disease	Hemangioblastoma of the cerebellum and retina, pheochromocytoma, renal cancer	Autosomal dominant; mutation of tumor-suppressor gene, *VHL* gene
Multiple endocrine neoplasia syndrome, type 1 (Wermer syndrome)	Parathyroid, pancreatic islet, and pituitary tumors	Autosomal dominant; mutation in *PYGM* tumor-suppressor gene
Multiple endocrine neoplasia syndrome, type 2A (Sipple syndrome)	Medullary carcinoma of the thyroid, hyperparathyroidism, pheochromocytoma	Autosomal dominant; mutations in CYS-rich regions of the *RET* gene activate this protooncogene; *RET* codes for a tyrosine kinase; monitor calcitonin and calcium levels
Multiple endocrine neoplasia type 2B (multiple mucosal neuroma syndrome)	Mucosal neuroma, pheochromocytoma, medullary thyroid carcinoma, Marfan habitus; neuropathy	Autosomal dominant; mutation in catalytic site (codon 883 or 914) activates protooncogene; *RET* codes for a tyrosine kinase
Familial adenomatous polyposis	Colorectal, thyroid carcinoma, duodenal and periampullar carcinomas; pediatric hepatoblastoma	Autosomal dominant; mutation in *APC* gene
Familial juvenile polyposis	Colorectal carcinoma	Autosomal dominant; mutation in *SMAD4* gene
Hereditary nonpolyposis colon cancer (Lynch syndrome, NHPCC)	Colon cancer	Autosomal dominant; mutation in mismatch repair genes; *hMSH2, hMLH1, PMS1, PMS2, hMSH6, hMSG3*
Turcot syndrome	Pediatric brain tumors and increased risk of colon carcinoma and polyps	Mutation in *APC* gene
Familial adenomatous polyposis coli	Adenocarcinoma of colon	Autosomal dominant, *APC* gene
Gardner syndrome	Adenocarcinoma of colon, skull and soft tissue tumors	Autosomal dominant, *APC* gene
Peutz-Jeghers syndrome	Gastrointestinal carcinoma, ovarian neoplasia	Autosomal dominant, *LKB1* gene codes for a Ser/Thr kinase that regulates cell cycle, metabolism, cell polarity
Hemochromatosis	Hepatocellular carcinoma	Autosomal dominant; malignancy associated with cirrhotic liver
Glycogen storage disease 1 (von Gierke disease)	Hepatocellular carcinoma	Autosomal recessive; malignancy associated with cirrhotic liver Mutation in glucose-6-phosphatase or glucose-6-phosphatase translocase genes
Tyrosinemia, galactosemia	Hepatocellular carcinoma	Autosomal recessive; tumor associated with cirrhotic liver
BRCA1 and *BRCA2*	Breast, ovarian	DNA repair defect
Diamond-Blackfan anemia	AML, myelodysplastic syndrome, osteogenic sarcoma	Autosomal dominant; family 9 genes encoding ribosomal proteins
Shwachman-Diamond syndrome	AML, myelodysplasia	Autosomal recessive; *SBDS* gene; chromosome 7q11.21
Hereditary diffuse gastric cancer	Gastric cancer	Autosomal dominant; *CDH1* gene
Pleuropulmonary blastoma family tumor and dysplasia syndrome (DICER1)	Pulmonary blastoma	Encoded protein is a ribonuclease required for microRNA processing
Hereditary neuroblastoma	Neuroblastoma	Two genes have been identified: • Anaplastic lymphoma kinase *(ALK)* at chromosome 2p23 • Paired-like homeobox 2b *(PHOX2B)* at chromosome 4q12
Hereditary paraganglioma–pheochromocytoma syndrome	Paraganglioma Pheochromocytomas	Mutation in the mitochondrial enzyme succinate dehydrogenase protein (SDH)
Congenital or cyclic neutropenia	Myelodysplastic syndrome AML	*ELANE* mutation at 19p13.3; elastase; neutrophil expressed

ALL, acute lymphocytic leukemia; AML, acute myelocytic leukemia; GI, gastrointestinal; GU, genitourinary; JMML, juvenile myelomonocytic leukemia; NHPCC, nonhereditary polyposis colon cancer.

The third category of inherited cancer predisposition is characterized by **defects in immune surveillance**. This group includes patients with Wiskott-Aldrich syndrome, severe combined immunodeficiency, common variable immunodeficiency, and the X-linked lymphoproliferative syndrome. The most common types of malignancy in these patients are lymphoma and leukemia. Cure rates for immunodeficient children with cancer are much poorer than for nonimmunodeficient children with similar malignancies, suggesting a role for the immune system in cancer treatment as well as in cancer prevention.

OTHER FACTORS ASSOCIATED WITH ONCOGENESIS

Viruses

Several viruses have been implicated in the pathogenesis of malignancy. The association of the Epstein-Barr virus (EBV) with Burkitt lymphoma and nasopharyngeal carcinoma was identified more than 30 yr ago, but EBV infection alone is not sufficient for malignant transformation. EBV is also associated with mixed cellularity and lymphocyte-depleted Hodgkin disease, as well as some T-cell lymphomas, which is particularly intriguing because EBV normally does not infect T lymphocytes. The most conclusive evidence for a role of EBV in lymphogenesis is the direct causal role of EBV for B-cell lymphoproliferative disease in immunocompromised persons, especially those with AIDS.

Children who are chronically infected with hepatitis B (hepatitis B surface antigen–positive) have a >200-fold increased risk of developing hepatocellular carcinoma. In adults, the latency period between viral infection and the development of hepatocellular carcinoma approaches 20 yr. However, in children who acquire the viral infection through perinatal transmission, the latency period can be as short as 6-7 yr. The additional factors that are required for the malignant transformation of the virally infected hepatocytes are not clear. Hepatitis C virus infection is another risk factor for hepatocellular carcinoma and is also associated with splenic lymphoma.

Nearly all cervical carcinomas contain human papillomavirus (HPV). High-risk HPVs include types 16 and 18 but also types 31, 33, 35, 45, and 56, which are also commonly found in women without lesions. The low-risk HPVs, including 6 and 11 that are commonly found in genital warts, are almost never associated with malignancies. Like other virus-associated cancers, the presence of HPV alone is not sufficient to cause malignant transformation. The mechanism by which HPV 19 induces malignant transformation is thought to involve *P53* and *RB* tumor-suppressor genes, which regulate the cell cycle by acting as gatekeepers of the G1/S and G2/M checkpoints. By interfering with these proteins, HPV alters the regulation of cell growth.

Human herpesvirus 8 is associated with Kaposi sarcoma, primary effusion B-cell lymphoma, and the plasma cell variant of Castleman disease, all of which occur primarily in persons with AIDS. Human T-cell leukemia virus 1 is associated with adult T-cell leukemia and lymphoma.

Genomic Imprinting

The development of cancer has also been linked to genomic imprinting, which is the selective inactivation of 1 of 2 alleles of a certain gene. The inactivated gene is determined by whether the gene is inherited from the mother or father. For example, normally the maternal *IGF2* (insulin-like growth factor receptor 2) gene is inactivated. The inactivation is thought to be secondary to methylation of specific CpG sequences upstream of the *IGF2* promoter, which interferes with the transcription of the *IGF2* gene. In some Wilms tumors, there is loss of methylation in the upstream area of the maternal gene, which, in turn, allows transcript expression of the maternal *IGF2* gene. At the same time the *H19* gene (whose function is not yet clear), a previously actively transcribed maternal gene, is silenced by methylation. Beckwith-Wiedemann syndrome, an overgrowth syndrome characterized by macrosomia, macroglossia, hemihypertrophy, omphalocele, and renal anomalies, is associated with an increased risk of Wilms tumor, hepatoblastoma, rhabdomyosarcoma, neuroblastoma, and adrenal cortical carcinoma. The increased risk in developing cancer is associated with changes in the methylation pattern of genes on the 11p15 chromosome. Studies indicate that methylation patterns in a given individual change over time and that specific groups of methylation changes tend to cluster within families, suggesting heritability of the pattern of changes.

Telomerase

Telomeres are a series of tens to thousands of TTAGGG repeats at the ends of chromosomes that are important for stabilizing the chromosomal ends and limiting breakage, translocation, and loss of DNA material. With DNA replication there is a progressive shortening of telomere length, which is a hallmark of cellular aging and may be a senescence signal. In some instances telomerase, an enzyme that adds telomeres to the ends of chromosomes, becomes active. The addition of telomeres can be found in immortalized cell lines and most tumor types, and as a consequence, these cells might have a survival advantage, allowing them to undergo additional cell divisions. Therapy aimed at inhibiting telomerase activity can result in cell death.

Chapter 493

Principles of Diagnosis

A. Kim Ritchey and Erika Friehling

Childhood cancer is uncommon and can manifest with symptoms seen with benign illnesses. The challenge for the pediatrician is to be alert to the clues suggesting a diagnosis of cancer. In addition to the classic manifestations, any persistent, unexplained symptom or sign should be evaluated as potentially emanating from a cancerous or precancerous condition. As part of the diagnostic evaluation, the pediatrician and pediatric oncologist must convey the possible diagnosis to the patient and family in a sensitive and informative manner.

SIGNS AND SYMPTOMS

The symptoms and signs of cancer are variable and nonspecific in pediatric patients. The types of cancer that occur during the 1st 20 yr of life vary dramatically as a function of age—more so than at any other comparable age range (see Chapter 491). Unlike cancers in adults, childhood cancers usually originate from the deeper, visceral structures and from the parenchyma of organs rather than from the epithelial layers that line the ducts and glands of organs and compose the skin. In children, dissemination of disease at diagnosis is common, and presenting symptoms or signs are often caused by systemic involvement. Pain was one of the initial presenting symptoms in more than 50% of children with cancer in one study. Infants and young children cannot express or localize their symptoms well. Another factor is the variability in the physiology and biology of the host that are related to growth and development during infancy, childhood, and adolescence.

The signs of cancer in children are often attributed to other causes before the malignancy is recognized. Delays in diagnosis are particularly problematic during late adolescence and are the result of a variety of factors prominent in this age group, including loss of health insurance coverage.

Although there is no clearly established set of warning signs of cancer in young people, the most common cancers in children suggest some guidelines that may be helpful in early recognition of signs and symptoms of cancer (Table 493-1). Most of the symptoms and signs are not specific and might represent other possibilities in a differential diagnosis. Nonetheless, these hints encompass the common cancers of childhood and have been very useful in early detection.

Table 493-1 Common Manifestations of Childhood Malignancies

	SIGNS AND SYMPTOMS	POTENTIAL ETIOLOGY	POSSIBLE ONCOLOGIC DIAGNOSIS
Constitutional/Systemic	Fever, persistent or recurrent infection, neutropenia	Bone marrow infiltration	Leukemia, neuroblastoma
	Fever of unknown origin, weight loss, night sweats	Lymphoma	Hodgkin and non-Hodgkin lymphoma
	Painless lymphadenopathy	Lymphoma, metastatic solid tumor	Leukemia, Hodgkin lymphoma, non-Hodgkin lymphoma, Burkitt lymphoma, thyroid carcinoma
	Hypertension	Renal or adrenal tumor	Neuroblastoma, pheochromocytoma, Wilms tumor
	Soft tissue mass	Local or metastatic tumor	Ewing sarcoma, osteosarcoma, neuroblastoma, thyroid carcinoma, rhabdomyosarcoma, Langerhans cell histiocytosis
Neurologic/Ophthalmologic	Headache with emesis, visual disturbances, ataxia, papilledema, cranial nerve palsies	Increased intracranial pressure	Primary brain tumor; metastasis
	Leukokoria (white pupil)	Retinal mass	Retinoblastoma
	Periorbital ecchymosis	Metastasis	Neuroblastoma
	Miosis, ptosis, heterochromia	Horner syndrome: compression of cervical sympathetic nerves	Neuroblastoma
	Opsoclonus myoclonus, ataxia	Neurotransmitters? Autoimmunity?	Neuroblastoma
	Exophthalmos, proptosis	Orbital tumor	Rhabdomyosarcoma, lymphoma, Langerhans cell histiocytosis
Respiratory/Thoracic	Cough, stridor, pneumonia, tracheal-bronchial compression; superior vena cava syndrome	Anterior mediastinal mass	Germ cell tumor, non-Hodgkin lymphoma, Hodgkin lymphoma
	Vertebral or nerve root compression; dysphagia	Posterior mediastinal mass	Neuroblastoma, neuroenteric cyst
Gastrointestinal	Abdominal mass	Adrenal, renal, or lymphoid tumor	Neuroblastoma, Wilms tumor, lymphoma
	Diarrhea	Vasoactive intestinal polypeptide	Neuroblastoma, ganglioneuroma
Hematologic	Pallor, anemia	Bone marrow infiltration	Leukemia, neuroblastoma
	Petechiae, thrombocytopenia	Bone marrow infiltration	Leukemia, neuroblastoma
Musculoskeletal	Bone pain, limp, arthralgia	Primary bone tumor, metastasis to bone	Osteosarcoma, Ewing sarcoma, leukemia, neuroblastoma
Endocrine	Diabetes insipidus, galactorrhea, poor growth	Neuroendocrine involvement of hypothalamus or pituitary gland	Adenoma, craniopharyngioma, prolactinoma, Langerhans cell histiocytosis

Modified from Marcdante KJ, Kliegman RM, Jenson HB, et al, editors: Nelson essentials of pediatrics, *ed 6, Philadelphia, 2011, WB Saunders, p. 588.*

PHYSICAL EXAMINATION

Physical examination findings in a child with malignancy are dependent on whether the cancer is systemic (see Table 493-1) or localized. The cancers most common in children involve the lymphohematopoietic system. When the bone marrow is compromised by malignancy (e.g., leukemia, disseminated neuroblastoma), typical findings include pallor from anemia; bleeding, petechiae, or purpura from thrombocytopenia or coagulopathy; cellulitis or other localized infection from leukopenia; skin nodules (especially in infants) and hepatosplenomegaly from malignant leukocytosis. Abnormalities found in lymphatic malignancies include peripheral adenopathy (Fig. 493-1) and signs of superior vena cava syndrome from an anterior mediastinal mass (Fig. 493-2), including respiratory distress, and facial and neck plethora and edema. Enlargement of cervical lymph nodes is common in children, but when persistent, progressive, and painless it often suggests lymphoma. In particular, supraclavicular adenopathy suggests underlying malignancy.

Abnormalities of the central nervous system that can indicate cancer include decreased level of consciousness, cranial nerve palsies, ataxia, afebrile seizures, ptosis, decreased visual activity, neuroendocrine deficits, and increased intracranial pressure, which may be diagnosed by the presence of papilledema (Fig. 493-3). Any focal neurologic deficit in the motor or sensory system, especially a decrease in cranial nerve function, should prompt further investigation for malignancy.

Abdominal masses can be divided into upper, middle, and lower locations. Malignancies in the upper abdomen include Wilms tumor, neuroblastoma, hepatoblastoma, germ cell tumors, and sarcomas. Enlargement of the liver or spleen from leukemia can be mistaken for an upper abdominal mass. Midabdominal masses include non-Hodgkin lymphoma, neuroblastoma, germ cell tumors, and sarcomas. Lower abdominal masses include ovarian tumors, germ cell tumors, and sarcomas.

Rhabdomyosarcoma commonly appears as an extremity mass, particularly in adolescents. These tumors can be deceptively benign in appearance, but as with all unexplained masses they require immediate attention. Sacrococcygeal masses in neonates are usually teratomas, which are usually benign but can undergo malignant transformation if not removed promptly. Neuroblastoma can present as "blueberry muffin" spots on the skin of neonates or as periorbital ecchymosis in older children.

Ophthalmologic presentation of malignancy includes a white pupillary reflex (Fig. 493-4) rather than the usual red reflection from

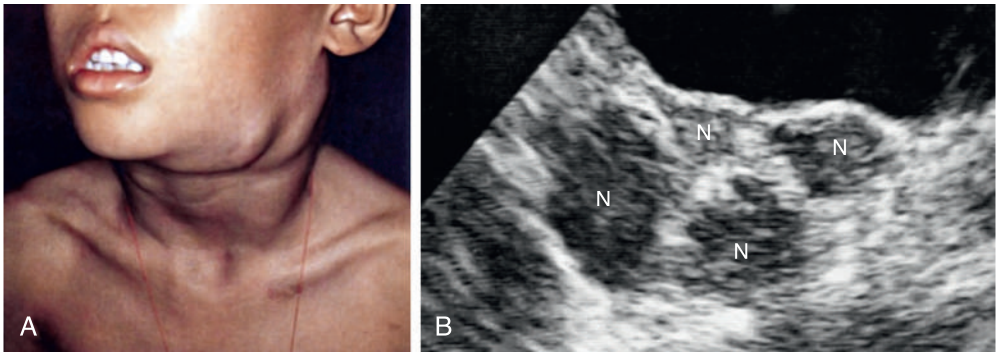

Figure 493-1 **Cervical lymphadenopathy.** Manifestations on physical examination **(A)** and on ultrasound examination **(B).** *N,* Abnormally enlarged lymph nodes. *(From Sinniah D, D'Angio GJ, Chatten J, et al:* Atlas of pediatric oncology, *London, 1996, Arnold.)*

incident light. A white pupillary reflex is essentially pathognomonic for retinoblastoma, although some benign conditions can mimic this finding. Proptosis can be produced by rhabdomyosarcoma, neuroblastoma, lymphoma, and Langerhans cell histiocytosis. Horner syndrome, iris heterochromia, and opsoclonus-myoclonus all suggest a diagnosis of neuroblastoma.

AGE-RELATED MANIFESTATIONS

Because various types of cancer in children occur at specific ages, the physician should tailor the history and physical examination based on the age of the child. The embryonal tumors, including neuroblastoma, Wilms tumor, retinoblastoma, hepatoblastoma, and rhabdomyosarcoma, usually occur during the 1st 2 yr of life (see Fig. 491-4). From 1-4 yr of age, acute lymphoblastic leukemia peaks in incidence. Brain tumors have a peak incidence in the 1st decade of life. Non-Hodgkin lymphomas are uncommon earlier than 5 yr of age but steadily increase thereafter. During adolescence, bone tumors, Hodgkin disease, and the gonadal and soft tissue sarcomas predominate. Hence, for infants and toddlers, special attention should be paid to the possibility of embryonal and intraabdominal tumors. Preschool-age and early school-age children showing compatible signs and symptoms should be specifically evaluated for leukemia. School-age children might present with lymphoma or with brain tumors. Adolescents require assessment for bone and soft tissue sarcomas and gonadal malignancies, as well as for Hodgkin lymphoma.

EARLY DETECTION

The prognosis of malignancy in children depends primarily on tumor type, extent of disease at diagnosis, and rapidity of response to treatment. Early diagnosis helps to ensure that appropriate therapy is given in a timely fashion and hence optimizes the chances of cure. Because most physicians in general practice rarely encounter children with undiagnosed cancer, they should remember to investigate the possibility of malignancy, especially when they encounter an atypical course of a common childhood condition, unusual manifestations that do not fit common conditions, and any persistent symptom that defies diagnosis.

Delays in diagnosis are particularly likely in certain clinical situations. The cardinal symptom of both osteosarcoma and Ewing sarcoma is localized and usually persistent pain. Because these tumors occur during the 2nd decade of life, a time of increased physical activity, patients often assume the pain results from trauma. Prompt radiologic evaluation can help confirm the diagnosis. Lymphoma, especially during adolescence, often manifests as an anterior mediastinal mass. Symptoms such as chronic cough, unexplained shortness of breath, or "new-onset asthma" are typical with this presentation and are often overlooked. Tumors of the nasopharynx or middle ear can mimic infection. Prolonged, unexplained ear pain, nasal discharge, retropharyngeal swelling, and trismus should be investigated as possible signs of malignancy.

Early symptoms of leukemia may be limited to prolonged or unexplained low-grade fever or bone and joint pain. Blood counts with abnormalities in two or more cell lines might indicate the need for bone marrow examination, even when leukemic blast cells are not seen in the blood smear (see Table 493-1).

Mass screening for children with malignancy is not feasible. A screening program to detect early-stage neuroblastoma was successful in documenting more cases of the disease, but it had no impact on overall outcome. However, certain children are at increased risk for cancer and require an individualized plan to ensure early detection of malignancy. Selected examples include children with certain chromosome abnormalities, such as Down syndrome, Klinefelter syndrome, WAGR syndrome (Wilms tumor, aniridia, genital abnormalities, and mental retardation); children with overgrowth syndromes, such as Beckwith-Wiedemann syndrome, and hemihypertrophy; children with certain inherited single-gene disorders, including retinoblastoma, *P53* mutations (Li-Fraumeni syndrome), familial adenomatous polyposis, and neurofibromatosis (see Table 492-2).

ENSURING THE DIAGNOSIS

When a malignant neoplasm is suspected, the immediate goal is to confirm the diagnosis. A tentative diagnosis can often be established on the basis of the patient's age, symptoms, and location of masses. Selected imaging techniques and tumor markers can facilitate the diagnostic approach (Table 493-2). Especially when a solid tumor is present,

the pediatric oncologist, surgeon, and pathologist should work as a team to determine the site of biopsy, amount of tissue required, and whether fine-needle aspiration, percutaneous image-guided biopsy, incisional biopsy, or excisional biopsy and tumor resection are indicated. For selected situations, at the time of the initial diagnostic procedure, plans for bone marrow aspiration and biopsy and placement of central venous access may be appropriate.

Pathologic evaluation of pediatric malignancies requires appropriate handling of tissue so that multiple different techniques can be used. It is important that fresh tissue not be placed in formalin. Besides routine light microscopy, pathologic evaluation may include immunochemistry, flow cytometry, cytogenetics, and molecular genetic studies (fluorescence in situ hybridization, reverse-transcriptase polymerase chain reaction). Emerging technologies include DNA microarray analysis and cancer genome sequencing that can identify specific gene expression patterns and sequences in tumors. In time, these technologies might ensure more accurate classification and treatment.

STAGING

Once a specific diagnosis is confirmed, studies to define the extent of the malignancy are necessary to determine prognosis and treatment. Table 493-2 outlines the minimum evaluation required for common pediatric malignancies. In addition, for many tumors (e.g., Wilms tumor, neuroblastoma, rhabdomyosarcoma) a surgical staging system is used. Surgical stage can be determined at the time of the initial diagnostic procedure or subsequently. For example, a patient who has abdominal surgery for possible Wilms tumor or neuroblastoma should have careful evaluation and biopsy of all adjacent lymph nodes. A child with rhabdomyosarcoma can require a subsequent biopsy of sentinel lymph nodes as determined by scintigraphy or dye injection adjacent to the primary tumor. The pathologist facilitates staging by examining margins of the specimen to determine residual tumor.

Chapter 494

Principles of Treatment

Archie Bleyer, A. Kim Ritchey, and Erika Friehling

Treatment of children with cancer begins with an absolute requirement for the correct diagnosis (including subtype), proceeds through accurate and thorough staging of the extent of disease and determination of prognostic subgroup, provides appropriate multidisciplinary and usually multimodal therapy, and requires assiduous evaluation of the possibilities of recurrent disease and of adverse late effects of the disease and the therapies rendered. Throughout treatment, every child with cancer should have the benefit of the expertise of specialized teams of providers of pediatric cancer care, including pediatric oncologists, pathologists, radiologists, surgeons, radiotherapists, nurses, and support staff, including nutritionists, social workers, psychologists, pharmacists, other medical specialists, and teachers trained to work with seriously ill children.

The best chance for cure of cancer is during the initial course of treatment; the cure rates for patients with recurrent disease are much lower than those for patients with primary disease. All patients with cancer should be referred to an appropriate specialized center as soon as possible when the diagnosis of cancer is suspected. All such centers in North America are identified on the Children's Oncology Group website (http://www.childrensoncologygroup.org) and on the National Cancer Institute cancer trials website (http://www.clinicaltrials.gov). The remarkable increases in cure rates for childhood malignancies since the 1970s would not have occurred without the collective participation of patients and their physicians in clinical research programs at these centers. In the United States, the National Cancer Institute's Clinical Trials Cooperative Groups Program is associated with a >80% reduction in the incidence of mortality from childhood cancer despite an overall increase in cancer incidence during this interval (Fig. 494-1). After what appeared to be a plateau in the rate of decline in mortality in the early 2000s, there is now evidence that the mortality rate

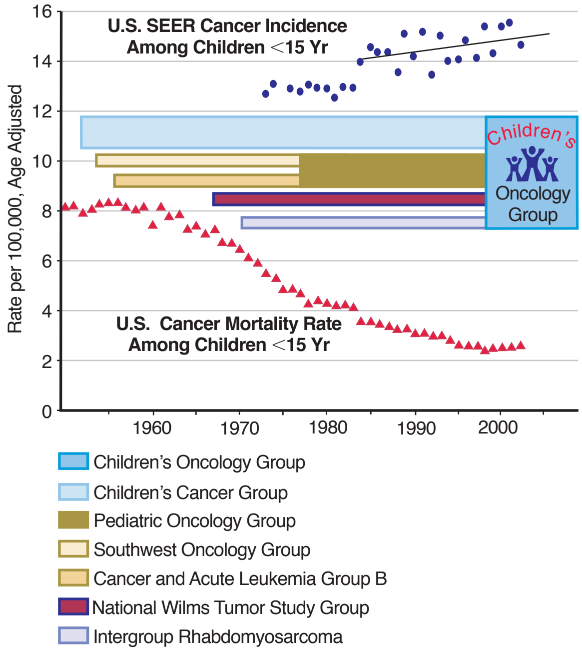

Figure 494-1 Reduction in the national cancer mortality rate among children younger than 15 yr of age *(triangles)* in the United States as a direct consequence of the National Cooperative Group Program sponsored by the National Cancer Institute, and in comparison to the rising incidence of cancer before age 15 yr *(circles)*. The *horizontal bars* indicate the duration of the existence of the national pediatric cancer cooperative groups, beginning with the Children's Cancer Group in 1955. Other groups are the Pediatric Oncology Group, which was derived from the Pediatrics Divisions of the Southwest Oncology Group and the Cancer and Acute Leukemia Group B, the National Wilms Tumor Study Group, and the Intergroup Rhabdomyosarcoma Study Group. In 2000, the 4 pediatric cooperative groups merged into the Children's Oncology Group. *(Incidence and mortality rate data from Ries LAG, Eisner MP, Kosary CL, et al, editors: SEER Cancer Statistics Review, 1975-2002, Bethesda, MD, National Cancer Institute;* http://seer.cancer.gov/csr/1975_2002/, *based on November 2004 SEER [Surveillance Epidemiology and End Results] data submission. The mortality rate data are national rates, and the incidence data are derived from the SEER program, representing approximately 15% of the United States. The most current information on treatment of all types of childhood cancer is available in the PDQ [Physician Data Query] on the National Cancer Institute website [http://www.cancer.gov/cancertopics/pdq/pediatrictreatment].)*

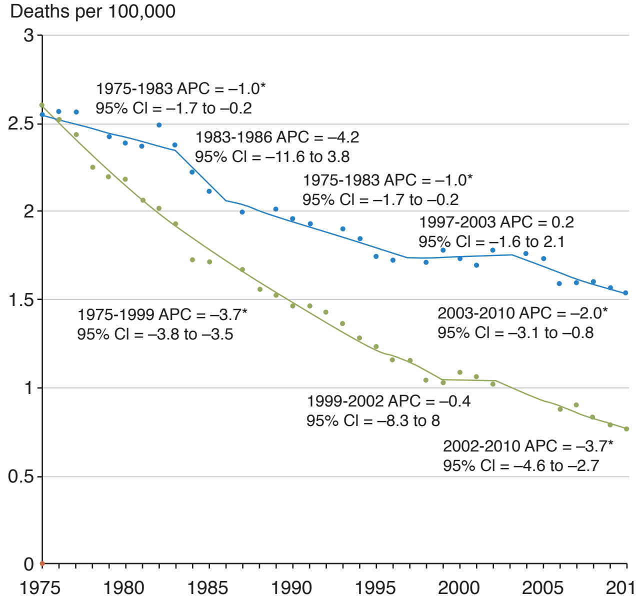

Figure 494-2 Age-adjusted mortality trends for all malignant cancers among children age <20 years in the United States from 1975 through 2010 along with annual percentage changes (APCs) for joinpoint segments. Asterisk indicates that the slope of the joinpoint segment is statistically different from zero ($P<.05$). The green line indicates leukemias and lymphomas, and the blue line indicates all other cancer sites. CI indicates confidence interval. *(From Smith MA, Altekruse SF, Adamson PC, et al: Declining childhood and adolescent cancer mortality,* Cancer *120:2497-2506, 2014.)*

continues to decline. Notably, a greater decline in mortality has been seen in the adolescent and young adult population when compared to children <15 yr old, reversing prior trends (Fig. 494-2). The most current information on treatment of all types of childhood cancer is available in the PDQ (Physician Data Query) on the National Cancer Institute website (http://www.cancer.gov/cancertopics/pdq/pediatrictreatment).

DIAGNOSIS AND STAGING

Accurate diagnosis and staging of the extent of disease are imperative, especially for childhood cancers that have high cure rates, because the nature of therapy depends strongly on the type of cancer. In addition, **prognostic subgroups** based on the stage of disease have been established for most cancers that occur in children. Accordingly, children with a better prognosis are treated with less-intensive therapy, including lower doses of chemotherapy or radiation therapy, a shorter duration of treatment, or elimination of at least one treatment modality (radiation therapy, chemotherapy, surgery). Accurate staging thus reduces the risk of excessive acute adverse effects and long-term complications of therapy in patients whose prognosis indicates that less therapy is required for cure. Overtreatment of patients with a more favorable prognosis is a definite risk if the patient is not referred to a cancer treatment center for management of adverse effects of such treatment. Conversely, undertreatment also is a clear risk if the diagnosis and stage are not correct, resulting in a compromise of an otherwise high potential for cure.

Diagnostic imaging is a critical phase of evaluation in most children with solid tumors (i.e., cancers other than leukemia). MRI, CT, ultrasonography, scintigraphy (nuclear medicine scans), positron emission tomography, and spectroscopy, as appropriate, all serve a clear purpose in the evaluation of children with cancer, not only before treatment to determine the extent of disease and the appropriate therapy but also during follow-up to determine whether the therapy was effective. In addition, response to treatment as determined by imaging techniques is being increasingly used to guide changes in the therapy.

Expertise in pathology and laboratory medicine provides critical diagnostic support and guides therapy in most children with cancer. Relatively noninvasive methods of obtaining tumor tissue (such as fine-needle aspiration and percutaneous image-guided biopsies) can be performed in pediatric centers with appropriate expertise in diagnostic imaging, interventional radiology, cytology, and anesthesia support. Sentinel node mapping is increasingly being applied in the staging of children's cancers. Determining the adequacy of surgery by evaluating frozen sections of the surgical margins for tumor cells is essential in many tumor operations.

A MULTIMODAL, MULTIDISCIPLINARY APPROACH

Many pediatric subspecialties are involved in the evaluation, treatment, and management of children with cancer, including provision of primary therapy and supportive care services (Fig. 494-3). More than two of the primary modalities are often used together, with chemotherapy being the most widely used, followed, in order of use, by surgery, radiation therapy, and biologic agent therapy (Fig. 494-4).

The leukemias that occur in childhood usually are managed with chemotherapy alone, with a small proportion of patients receiving cranial or craniospinal radiation therapy to prevent or treat overt central nervous system (CNS) leukemia. Children with non-Hodgkin

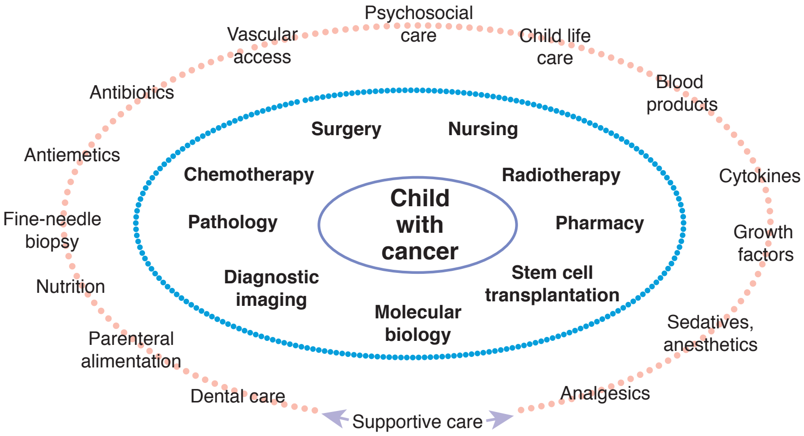

Figure 494-3 Multidisciplinary care of children with cancer. The *inner circle* designates primary modalities, and the *outer ring* identifies supportive care elements to which all children with cancer have access.

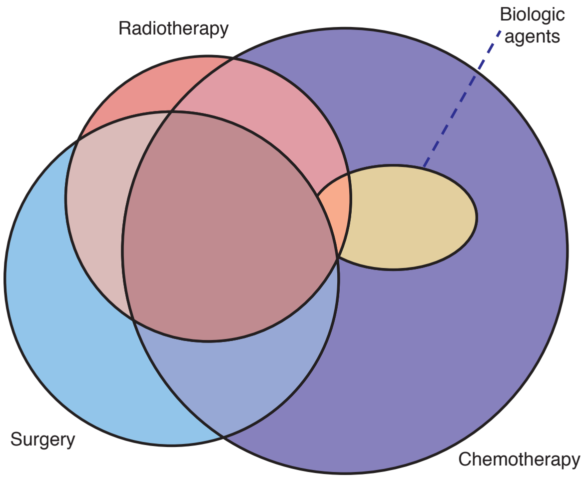

Figure 494-4 The primary modalities of therapy used in the treatment of children with cancer. The relative sizes of the circles designate the approximate proportion of overall role in the management of pediatric cancers.

lymphoma also are treated with chemotherapy alone, with the exception of radiation therapy for CNS involvement. Localized therapy with surgery or irradiation, or both, is an important component of treatment of most solid tumors, including Hodgkin lymphoma, but systemic multiagent chemotherapy usually is necessary because tumor dissemination generally is present even if it is undetectable. Chemotherapy alone usually is not adequate to eradicate gross residual tumors. Hence, it is not unusual for children with malignant tumors to require treatment with all 3 modalities (see Fig. 494-3). Unfortunately, most treatments that are effective in children with cancer have a narrow therapeutic index (a low ratio of efficacy to toxicity). The acute and chronic adverse effects of these treatments can be minimized but not entirely avoided.

Biologic agent therapy has become an important modality in a few childhood cancers (see Fig. 494-4). This type of treatment generally refers to immunotherapy, biologic response modifiers, or endogenously occurring molecules that have therapeutic effects in supraphysiologic doses. Examples are retinoic acid therapy in acute promyelocytic leukemia, monoclonal antibody therapy for neuroblastoma and certain non-Hodgkin lymphomas, tyrosine kinase inhibitors such as imatinib mesylate for chronic myelogenous and Philadelphia chromosome–positive leukemias, and radioactive metaiodobenzylguanidine therapy for neuroblastoma.

Chemotherapy is used more widely in children than in adults because children better tolerate the acute adverse effects and the malignant diseases that occur in childhood are more responsive to chemotherapy than are malignant diseases of adults. Radiation therapy is used sparingly in children because they are more vulnerable than adults to its late adverse effects.

Whenever possible, treatment is given on an outpatient basis. Children should remain living at home and in school as much as possible throughout treatment. Increasingly, pediatric cancer therapies are being administered to ambulatory patients, with the advent of such innovations as programmable infusion pumps, oral chemotherapeutic regimens, early discharge from hospital with intensive outpatient supportive care, and home healthcare services. Some patients miss a considerable amount of school in the 1st yr after diagnosis because of the intensity of therapy or its adverse effects and of the ensuing complications of the disease or therapy. Tutoring should be encouraged so that children do not fall behind in their schooling; counseling should be provided as appropriate. In-hospital school services should be provided for patients who must spend much of their time as inpatients receiving therapy for disease or for managing adverse effects.

Development of selective, highly effective therapy for cancer in both children and adults had been hindered by a lack of understanding of the molecular mechanisms that underlie malignant transformation. De novo or acquired resistance to chemotherapy and radiation therapy remains an obstacle to cure. Ongoing discoveries of molecular and cellular mechanisms that explain the cancer process have led to increasingly specific antineoplastic therapies, generally referred to as **molecularly targeted therapies.** Their most prominent feature is a relative lack of normal tissue toxicity, such that the additional therapeutic benefit occurs with minimum additional toxicity. Many of the new biologic agent therapies, such as imatinib and rituximab, fall into this category (Table 494-1). **Complementary** and **alternative remedies** are increasingly being provided by parents to their children with cancer, with or without knowledge of the medical professionals entrusted with the child's care (see Chapter 64). Many of these have not been evaluated by rigorous testing and most are ineffective; some are toxic or interfere with the metabolism of other drugs.

DISCUSSING THE TREATMENT PLAN WITH THE PATIENT AND FAMILY

The diagnostic and treatment plan must be carefully explained to parents and, if the child is old enough to understand, to the patient. An honest discussion of the facts is the best policy. Children should be given as much information as they can understand and would find useful or that information they express a desire or wish to know. Effects of treatment, such as the possible need to amputate a limb, loss of hair during chemotherapy, and possible temporary or permanent functional impairment must be anticipated and fully discussed. The possibility and probability of death from cancer should be covered in an age-appropriate manner. It usually is necessary to repeat explanations several times before distraught family members fully understand. Throughout treatment, parents, patients, siblings, and medical staff will need help in expressing feelings of anxiety, depression, guilt, and anger. The pediatrician, pediatric oncologist, and nurses should call on experienced professionals, including pediatric social workers, child

psychologists and psychiatrists, child-life specialists, and schoolteachers with special expertise in managing students with cancer to assist when needed.

TREATMENTS

Chemotherapy

The most widely used modality in pediatric cancer therapy is chemotherapy (see Fig. 494-3). Therapy nearly always involves combinations of drugs, such as VAC (vincristine, dactinomycin [Actinomycin D], and cyclophosphamide) and CHOP (cyclophosphamide, doxorubicin [hydroxydaunorubicin/Adriamycin], vincristine [Oncovin], and prednisone). Sequential single-drug therapy rarely results in complete responses, and partial responses usually are infrequent and transient and grow progressively shorter in duration with each drug used. Combination chemotherapy is the standard when combinations of drugs with different mechanisms of action and non-overlapping toxicities were first demonstrated to be effective in childhood leukemia. Most of the cytotoxic drugs for childhood cancer are selected from several classes of agents, including alkylating agents, antimetabolites, antibiotics, hormones, plant alkaloids, and topoisomerase inhibitors (Table 494-2). The increased metabolic and cell-cycle activity of malignant cells makes them more susceptible to the cytotoxic effects of these types of agents (Fig. 494-5).

Because most antineoplastic agents are cell-cycle dependent, their adverse effects usually are related to the proliferation kinetics of individual cell populations. Most susceptible are tissues or organs with high rates of cell turnover: bone marrow, oral and intestinal mucosa, epidermis, liver, and spermatogonia. The most common acute adverse

Table 494-2 Common Chemotherapeutic Agents Used in Children

DRUG	MECHANISM OF ACTION OR CLASSIFICATION	INDICATION(S)	ADVERSE REACTIONS (PARTIAL LIST)	COMMENTS
Methotrexate	Folic acid antagonist; inhibits dihydrofolate reductase	ALL, non-Hodgkin lymphoma, osteosarcoma, Hodgkin lymphoma, medulloblastoma	Myelosuppression, mucositis, stomatitis, dermatitis, hepatitis With long-term administration; osteopenia and bone fractures With high-dose administration; renal and CNS toxicity With intrathecal administration; arachnoiditis, leukoencephalopathy, leukomyelopathy	Systemic administration may be PO, IM, or IV; also may be administered intrathecally Plasma methotrexate levels must be monitored with high-dose therapy and when low doses are administered to patients with renal dysfunction, and leucovorin rescue applied accordingly
6-Mercaptopurine (Purinethol)	Purine analog; inhibits purine synthesis	ALL	Myelosuppression, hepatic necrosis, mucositis; allopurinol increases toxicity	Allopurinol inhibits metabolism
Cytarabine (cytosine arabinoside; Ara-C)	Pyrimidine analog; inhibits DNA polymerase	ALL, AML, non-Hodgkin lymphoma, Hodgkin lymphoma	Nausea, vomiting, myelosuppression, conjunctivitis, mucositis, CNS dysfunction With intrathecal administration; arachnoiditis, leukoencephalopathy, leukomyelopathy	Systemic administration may be PO, IM, or IV; may also be administered intrathecally
Cyclophosphamide (Cytoxan)	Alkylates guanine; inhibits DNA synthesis	ALL, non-Hodgkin lymphoma, Hodgkin lymphoma, soft tissue sarcoma, Ewing sarcoma, Wilms tumor, neuroblastoma	Nausea, vomiting, myelosuppression, hemorrhagic cystitis, pulmonary fibrosis, inappropriate ADH secretion, bladder cancer, anaphylaxis	Requires hepatic activation and thus is less effective in presence of liver dysfunction. Mesna prevents hemorrhagic cystitis
Ifosfamide (Ifex)	Alkylates guanine; inhibits DNA synthesis	Non-Hodgkin lymphoma, Wilms tumor, soft tissue sarcoma	Nausea, vomiting, myelosuppression, hemorrhagic cystitis, pulmonary fibrosis, inappropriate ADH secretion, CNS dysfunction, cardiac toxicity, anaphylaxis	Mesna prevents hemorrhagic cystitis

Continued

Table 494-2 Common Chemotherapeutic Agents Used in Children—cont'd

DRUG	MECHANISM OF ACTION OR CLASSIFICATION	INDICATION(S)	ADVERSE REACTIONS (PARTIAL LIST)	COMMENTS
Doxorubicin (Adriamycin), daunorubicin (Cerubidine), and idarubicin (Idamycin)	Binds to DNA, intercalation	ALL, AML, osteosarcoma, Ewing sarcoma, Hodgkin lymphoma, non-Hodgkin lymphoma, neuroblastoma	Nausea, vomiting, cardiomyopathy, red urine, tissue necrosis on extravasation, myelosuppression, conjunctivitis, radiation dermatitis, arrhythmia	Dexrazoxane reduces risk of cardiotoxicity
Dactinomycin	Binds to DNA, inhibits transcription	Wilms tumor, rhabdomyosarcoma, Ewing sarcoma	Nausea, vomiting tissue necrosis on extravasation, myelosuppression, radiosensitizer, mucosal ulceration	
Bleomycin (Blenoxane)	Binds to DNA, cleaves DNA strands	Hodgkin disease, non-Hodgkin lymphoma, germ cell tumors	Nausea, vomiting, pneumonitis, stomatitis, Raynaud phenomenon, pulmonary fibrosis, dermatitis	
Vincristine (Oncovin)	Inhibits microtubule formation	ALL, non-Hodgkin lymphoma, Hodgkin disease, Wilms tumor, Ewing sarcoma, neuroblastoma, rhabdomyosarcoma	Local cellulitis, peripheral neuropathy, constipation, ileus, jaw pain, inappropriate ADH secretion, seizures, ptosis, minimal myelosuppression	IV administration only; must not be allowed to extravasate
Vinblastine (Velban)	Inhibits microtubule formation	Hodgkin lymphoma, non-Hodgkin lymphoma, Langerhans cell histiocytosis, CNS tumors	Local cellulitis, leukopenia	IV administration only; must not be allowed to extravasate
L-Asparaginase	Depletion of L-asparagine	ALL; AML, when used in combination with cytarabine	Allergic reaction pancreatitis, hyperglycemia, platelet dysfunction and coagulopathy, encephalopathy	PEG-asparaginase now preferred to L-asparaginase
Pegaspargase (Oncaspar)	Polyethylene glycol conjugate of L-asparagine	ALL	Indicated for prolonged asparagine depletion and for patients with allergy to L-asparaginase	
Prednisone and dexamethasone (Decadron)	Lymphatic cell lysis	ALL; Hodgkin lymphoma, non-Hodgkin lymphoma	Cushing syndrome, cataracts, diabetes, hypertension, myopathy, osteoporosis, avascular necrosis, infection, peptic ulceration, psychosis	
Carmustine (BiCNU)	Carbamylation of DNA; inhibits DNA synthesis	CNS tumors, non-Hodgkin lymphoma, Hodgkin lymphoma	Nausea, vomiting, delayed myelosuppression (4-6 wk); pulmonary fibrosis, carcinogenic stomatitis	Phenobarbital increases metabolism, decreases activity
Carboplatin and cisplatin (Platinol)	Inhibits DNA synthesis	Osteosarcoma, neuroblastoma, CNS tumors, germ cell tumors	Nausea, vomiting, renal dysfunction, myelosuppression, ototoxicity, tetany, neurotoxicity, hemolytic-uremic syndrome, anaphylaxis	Aminoglycosides may increase nephrotoxicity
Etoposide (VePesid)	Topoisomerase inhibitor	ALL, non-Hodgkin lymphoma, germ cell tumor, Ewing sarcoma	Nausea, vomiting, myelosuppression, secondary leukemia	
Tretinoin (all *trans*-retinoic acid); and isotretinoin (cis-retinoic acid; Accutane)	Enhances normal differentiation	Acute promyelocytic leukemia; neuroblastoma	Dry mouth, hair loss, pseudotumor cerebri, premature epiphyseal closure, birth defects	

ADH, antidiuretic hormone; ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CNS, central nervous system; PEG, polyethylene glycol.

effects are myelosuppression (with neutropenia and thrombocytopenia being the most problematic), immunosuppression, nausea and vomiting, hepatic dysfunction, upper and lower gastrointestinal mucositis, dermatitis, and alopecia. Fortunately, the tissues affected also recover relatively quickly, so that the acute adverse effects are nearly always reversible. Life-threatening effects of many chemotherapy agents include severe neutropenia with infection, fungemia or fungal pneumonia as a result of immunosuppression, and septicemia, not infrequently linked to indwelling intravascular devices (Table 494-3; see Chapters 178 and 179). Cardiomyopathy caused by anthracyclines (e.g., doxorubicin and daunorubicin) and renal failure from platinum-containing agents also may be life-threatening or disabling.

Table 494-3 Infectious Complications of Malignancy

PREDISPOSING FACTOR	ETIOLOGY	SITE OF INFECTION	INFECTIOUS AGENTS
Neutropenia	Chemotherapy, bone marrow infiltration	Sepsis, shock, pneumonia, soft tissue, proctitis, mucositis	*Streptococcus viridans, Staphylococcus aureus, Staphylococcus epidermidis, Escherichia coli, Pseudomonas aeruginosa, Candida, Aspergillus,* anaerobic oral and rectal bacteria
Immunosuppression, lymphopenia, lymphocyte-monocyte dysfunction	Chemotherapy, corticosteroid	Pneumonia, meningitis, disseminated viral infection	*Pneumocystis jiroveci, Cryptococcus neoformans, Mycobacterium, Nocardia, Listeria monocytogenes, Candida, Aspergillus, Strongyloides, Toxoplasma,* varicella-zoster virus, cytomegalovirus, herpes simplex
Indwelling central venous catheter	Nutrition, administration of chemotherapy	Line sepsis, tract of tunnel, exit site	*S. epidermidis, S. aureus, Candida albicans, P. aeruginosa, Aspergillus, Corynebacterium, Streptococcus faecalis, Mycobacterium fortuitum, Propionibacterium acnes*

Modified from Kliegman RM, Marcdante KJ, Jenson HB, et al, editors: Nelson essentials of pediatrics, *ed 6, Philadelphia, 2011, WB Saunders, Chapter 121.*

Least susceptible to chemotherapy and radiation therapy are cells that do not replicate or that replicate slowly, such as neurons, muscle cells, connective tissue, and bone. However, children are not exempt from toxicities of these tissues, probably because they are still undergoing proliferation, albeit at a slower pace than other tissues, during growth and growth spurts.

Physically, children can endure the acute adverse effects of chemotherapy better than adults can in many ways. The maximum tolerated dosage in children, when expressed on the basis of body surface area or body weight, commonly is greater than that in adults. A comparison of anticancer drugs tested in phase I trials in both adult and pediatric patients showed that the maximum tolerated dosage in children was greater than that in adults for 70% of the agents, equal to that in adults for 15% of the agents, and less than the adult dose for only 15% of the agents. For all the drugs that were compared, the mean pediatric maximum tolerated dosage was greater than the adult mean.

Tumor-directed therapies are evolving in the field of pediatric oncology. Tumor antigen–specific monoclonal antibodies have been incorporated into the standard therapy of neuroblastoma (anti–ganglioside GD_2). The antiangiogenic agent bevacizumab (monoclonal antibody against vascular endothelial growth factor A) shows promise in the treatment of CNS tumors, especially low-grade gliomas.

Surgery

Superb pediatric surgical and anesthesia services are indispensable for children with cancer. The pediatric surgeon's role varies, depending on the type of tumor. For solid tumors, complete resection with

documented evidence of negative margins often is required for cure or long-term control. Considerable prolongation of life nearly always depends on whether the tumor is resectable and on the actual extent of resection.

With the exception of brainstem tumors and retinoblastoma, all solid tumors in children require a tissue diagnosis; therefore, biopsy of the suspected neoplasm is paramount. Staging with sentinel node biopsies has become the standard of care for several pediatric malignancies. Surgical expertise is essential for implantation of vascular access devices and removal and replacement of such devices when infection or thrombosis supervenes (see Chapter 179).

Increasingly, minimally invasive endoscopic surgical techniques are being used when indicated and, if the patient's condition permits, for biopsy and resection of tumor, direct ascertainment of residual disease and assessment of response, lysis of adhesions, and splenectomy.

Radiation Therapy

Radiation therapy is used sparingly in children, who are more susceptible than are adults to the adverse delayed effects of ionizing radiation. A major advance in pediatric radiation therapy is the application of **conformal irradiation** to children with cancer. This technique, most commonly applied as **intensity-modulated radiation therapy,** spares normal tissue by conforming the radiation volume to the shape of the tumor, thereby enabling delivery of higher doses to the tumor with lower exposure of normal tissue adjacent to the tumor or in the path of the radiation beam. Another example is proton-beam radiotherapy, which has just begun to be more widely available for children with cancer. With more focused beams and better sedation and immobilization techniques, radiation therapy is becoming more commonly used in children. Acute adverse effects from radiation therapy are less severe than those from chemotherapy and depend on which part of the body is irradiated and the means of administration. Dermatitis is the most common general adverse effect, because skin is always in the treatment field. Nausea and diarrhea are common subacute adverse effects with abdominal radiation therapy. Mucositis nearly always occurs to some extent whenever oral or intestinal mucosa is in the treatment volume. Somnolence is common with cranial irradiation. Alopecia occurs where hair is in the radiation field.

Most radiation therapy schedules require treatment 5 days per week for 4-7 wk, depending on the dose needed to control the tumor and on the amount and nature of normal tissue in the field. Most adverse effects are not noted until the second half of the course of irradiation. Late effects can occur months to years after radiation therapy and usually are dose-limiting manifestations. The type of delayed toxicity also depends on the site of irradiation. Examples are impaired growth resulting from cranial or vertebral irradiation, endocrine dysfunction from midbrain irradiation, pulmonary or cardiac insufficiency from chest irradiation, strictures and adhesions from abdominal irradiation, and infertility from pelvic irradiation. Second malignancy can also develop in the radiation field, for example, breast cancer from chest irradiation and brain tumors from CNS irradiation.

ACUTE TOXIC EFFECTS AND SUPPORTIVE CARE

Adverse treatment effects that occur early in therapy can result in oncologic emergencies. These include metabolic disorders, bone marrow suppression, and compression by tumors on vital structures (Table 494-4). In tumor lysis syndrome (TLS), uric acid, phosphates, and potassium are released in the circulation in large quantities from death of tumor cells. Hyperuricemia can lead to impairment of renal function, which further exacerbates the metabolic abnormalities. TLS can occur before therapy in patients with a large tumor burden (e.g., Burkitt lymphoma, lymphoblastic lymphoma, and high white blood cell count leukemia), but it is usually seen within 12-48 hr of initiating chemotherapy. TLS is infrequently reported in other tumors (Hodgkin lymphoma, neuroblastoma, hepatoblastoma). Before therapy is initiated, the serum levels of uric acid, electrolytes, calcium, phosphorus, and creatinine should be measured and adequate hydration ensured. Allopurinol (a xanthine oxidase inhibitor) should be started to prevent further accumulation of uric acid. In patients with established TLS with high uric acid levels or those at high risk for TLS, rasburicase (an enzyme that degrades uric acid) should be given instead of allopurinol. Symptomatic hyperkalemia and hyperphosphatemia with subsequent hypocalcemia can develop in the setting of inadequate renal function.

Virtually all chemotherapy regimens can produce **myelosuppression,** as can malignancies that invade and replace bone marrow. Anemia can be corrected by transfusions of packed erythrocytes, and thrombocytopenia can be corrected by platelet infusions. Patients receiving immunosuppressive therapy should receive irradiated blood products to prevent graft-versus-host disease and leukoreduced blood products to prevent transfusion-associated reactions and infections. Neutropenia (neutrophil counts <500/µL) poses a risk of life-threatening infection. Febrile neutropenic patients should be hospitalized and treated with empiric broad-spectrum intravenous antimicrobial therapy pending the results of appropriate cultures of blood, urine, or any obvious sites of infection (see Chapter 178). Treatment is continued until fever resolves and the neutrophil count rises. If fever persists for more than 3-5 days while the patient is receiving broad-spectrum antibiotics, the possibility of fungal infection must be considered. Fungal infections caused by *Candida* and *Aspergillus* are common in immunosuppressed patients. Opportunistic organisms such as *Pneumocystis jiroveci* can produce fatal pneumonia. Prophylactic treatment with trimethoprim-sulfamethoxazole is given when severe or prolonged immunosuppression is anticipated.

Viruses of low pathogenicity can produce serious disease in the setting of immunosuppression caused by malignancy or its treatment. Patients should not be given live virus vaccines. Children who are receiving chemotherapy and who are exposed to chickenpox should receive varicella-zoster immunoglobulin, or, if varicella-zoster immunoglobulin is not available, oral acyclovir should be considered. If clinical disease develops, the child should be hospitalized and treated with intravenous acyclovir.

Adequate **pain management** is critical. The World Health Organization (WHO) guidelines are particularly useful in the management of pain associated with cancer and cancer therapy (see Chapter 62).

Depending on the type of cancer therapy, patients can lose more than 10% of body weight. Patients sometimes reduce their food intake because of temporary, treatment-associated nausea, stomatitis, and vomiting. Appetite loss is not a cause for alarm. Malnutrition is a particular risk in patients receiving radiation therapy involving the abdomen or the head and neck, intensive chemotherapy, or total-body irradiation and high-dose chemotherapy before marrow transplantation. If oral supplementation proves inadequate, such patients can require enteral tube feedings or parenteral hyperalimentation.

LATE ADVERSE EFFECTS

Injury to tissues with low repair potential often results in long-lasting or permanent deficit. These effects can be either from the tumor or its treatment. For example, a brain or spinal tumor can leave the child with a permanent paresis or autonomic dysfunction, anthracycline-induced cardiomyopathy usually produces refractory cardiac dysfunction, and the leukoencephalopathy caused by intrathecal methotrexate and by CNS radiation therapy often is only partially reversible. The potential types of late adverse effects depend on the child's age at the time of treatment, the location(s) of the cancer, and the therapy administered. A good resource for the pediatrician, patient, and family who have to anticipate the possibilities is available at http://www.survivorshipguidelines.org.

Late adverse effects of therapy can cause substantial morbidity (Table 494-5). Successful surgical resection can result in loss of important functional structures. Irradiation can produce irreversible organ damage, with symptoms and functional limitations depending on the organ involved and the severity of the damage. Many problems related to radiation therapy do not become obvious until the patient is fully grown, such as asymmetry between irradiated and nonirradiated areas or extremities. Irradiation of fields that include endocrine organs can cause hypothyroidism, pituitary dysfunction, or infertility. In sufficient

Table 494-4 Oncologic Emergencies

CONDITION	MANIFESTATIONS	ETIOLOGY	MALIGNANCY	TREATMENT
METABOLIC				
Hyperuricemia	Uric acid nephropathy	Tumor lysis syndrome	Lymphoma, leukemia	Allopurinol, alkalinize urine; hydration and diuresis, rasburicase
Hyperkalemia	Arrhythmias, cardiac arrest	Tumor lysis syndrome	Lymphoma, leukemia	Kayexalate, sodium bicarbonate, glucose, and insulin; check for pseudohyperkalemia from leukemic cell lysis in test tube
Hyperphosphatemia	Hypocalcemic tetany; metastatic calcification, photophobia, pruritus	Tumor lysis syndrome	Lymphoma, leukemia	Hydration, forced diuresis; stop alkalinization; oral aluminum hydroxide to bind phosphate
Hyponatremia	Seizure, lethargy (may also be asymptomatic)	SIADH; fluid, sodium losses in vomiting	Leukemia, CNS tumor	Restrict free water for SIADH; replace sodium if depleted
Hypercalcemia	Anorexia, nausea, polyuria, pancreatitis, gastric ulcers; prolonged PR, shortened QT interval	Bone resorption; ectopic parathormone, vitamin D, or prostaglandins	Metastasis to bone, rhabdomyosarcoma, leukemia	Hydration and furosemide diuresis; corticosteroids; calcitonin, bisphosphonates
HEMATOLOGIC				
Anemia	Pallor, weakness, heart failure	Bone marrow suppression or infiltration; blood loss	Any with chemotherapy	Packed red blood cell transfusion
Thrombocytopenia	Petechiae, hemorrhage	Bone marrow suppression or infiltration	Any with chemotherapy	Platelet transfusion
Disseminated intravascular coagulation	Shock, hemorrhage	Sepsis, hypotension, tumor factors	Promyelocytic leukemia, others	Fresh-frozen plasma; platelets, cryoprecipitate, treat underlying disorder
Neutropenia	Infection	Bone marrow suppression or infiltration	Any with chemotherapy	If febrile, administer broad-spectrum antibiotics, and filgrastim (G-CSF) if appropriate
Hyperleukocytosis (>100,000/mm^3)	Hemorrhage, thrombosis; pulmonary infiltrates, hypoxia; tumor lysis syndrome	Leukostasis; vascular occlusion	Leukemia	Leukapheresis; chemotherapy; hydroxyurea
Graft-versus-host disease	Dermatitis, diarrhea, hepatitis	Immunosuppression and nonirradiated blood products; bone marrow transplantation	Any with immunosuppression	Corticosteroids; cyclosporine; tacrolimus; antithymocyte globulin
SPACE-OCCUPYING LESIONS				
Spinal cord compression	Back pain ± radicular *Cord above T10:* symmetric weakness, increased deep tendon reflex; sensory level present; toes up *Conus medullaris (T10-L2):* symmetric weakness, increased knee reflexes; decreased ankle reflexes; saddle sensory loss; toes up or down *Cauda equina (below L2):* asymmetric weakness; loss of deep tendon reflex and sensory deficit; toes down	Metastasis to vertebra and extramedullary space	Neuroblastoma; medulloblastoma	MRI or myelography for diagnosis; corticosteroids; radiotherapy; laminectomy; chemotherapy
Increased intracranial pressure	Confusion, coma, emesis, headache, hypertension, bradycardia, seizures, papilledema, hydrocephalus; cranial nerves III and VI palsies	Primary or metastatic brain tumor	Neuroblastoma, astrocytoma; glioma	CT or MRI for diagnosis; corticosteroids; phenytoin; ventriculostomy tube; radiotherapy; chemotherapy
Superior vena cava syndrome	Distended neck veins plethora, edema of head and neck, cyanosis, proptosis, Horner syndrome	Superior mediastinal mass	Lymphoma	Chemotherapy; radiotherapy
Tracheal compression	Respiratory distress	Mediastinal mass compressing trachea	Lymphoma	Radiation, corticosteroids

CNS, Central nervous system; G-CSF, granulocyte colony-stimulating factor; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Table 494-5 Late Effects and High-Risk Features of Childhood Cancer and Its Treatment

LATE EFFECTS	EXPOSURE	SELECTED HIGH-RISK FACTORS	AT-RISK DIAGNOSTIC GROUPS
NEUROCOGNITIVE			
Neurocognitive deficits Functional deficits in: • Executive function • Sustained attention • Memory • Processing speed • Visual-motor integration Learning deficits Diminished IQ Behavioral change	Chemotherapy: • Methotrexate Radiation affecting brain: • Cranial • Ear/infratemporal • Total-body irradiation (TBI)	Age <3 yr at time of treatment Female sex Supratentorial tumor Premorbid or family history of learning or attention problems Radiation doses >24 Gy Whole-brain irradiation	Acute lymphoblastic leukemia Brain tumor Sarcoma (head and neck or osteosarcoma)
NEUROSENSORY			
Hearing loss, sensorineural	Chemotherapy: • Cisplatin • Carboplatin Radiation affecting hearing: • Cranial • Infratemporal • Nasopharyngeal	Higher cisplatin dose (360 mg/m^2) Higher radiation dose impacting ear (>30 Gy) Concurrent radiation and cisplatin	Brain tumor Germ cell tumor Sarcoma (head and neck) Neuroblastoma Hepatoblastoma
Hearing loss, conductive Tympanosclerosis Otosclerosis Eustachian tube dysfunction	Radiation affecting hearing: • Cranial • Infratemporal • Nasopharyngeal	Higher radiation dose affecting ear (>30 Gy)	Brain tumor Sarcoma (head and neck)
Visual impairment Cataracts Lacrimal duct atrophy Xerophthalmia Retinopathy Glaucoma	Chemotherapy: • Busulfan • Glucocorticoids Radiation affecting eye: • Cranial • Orbital/eye • TBI	Higher radiation dose impacting eye (≥15 Gy for cataracts; >45 Gy for retinopathy and visual impairment)	Brain tumor Acute lymphoblastic leukemia Retinoblastoma Rhabdomyosarcoma (orbital) Allogeneic HSCT
Peripheral neuropathy, sensory	Chemotherapy: • Vincristine • Vinblastine • Cisplatin • Carboplatin	Higher cisplatin dose (≥300 mg/m^2)	Acute lymphoblastic leukemia Brain tumor Hodgkin lymphoma Germ cell tumor Non-Hodgkin lymphoma Sarcoma Neuroblastoma Wilms tumor Carcinoma
NEUROMOTOR			
Peripheral neuropathy, motor	Chemotherapy: • Vincristine • Vinblastine		Acute lymphoblastic leukemia Hodgkin lymphoma Non-Hodgkin lymphoma Sarcoma Brain tumor Neuroblastoma Wilms tumor
ENDOCRINE			
GH deficiency Precocious puberty	Radiation affecting HPA: • Cranial • Orbital/eye	Female sex Radiation dose to HPA >18 Gy	Acute lymphoblastic leukemia Sarcoma (facial) Carcinoma (nasopharyngeal)
Obesity	Ear/infratemporal Nasopharyngeal	Female sex Younger age (<4 yr)	Acute lymphoblastic leukemia
Hypothyroidism, central Gonadotropin deficiency Adrenal insufficiency, central	TBI	Radiation dose to HPA >18 Gy	Brain tumor Sarcoma (facial) Carcinoma (nasopharyngeal)
Hypothyroidism, primary	Neck, mantle irradiation	Radiation dose to thyroid >20 Gy	Hodgkin lymphoma

Table 494-5 Late Effects and High-Risk Features of Childhood Cancer and Its Treatment—cont'd

LATE EFFECTS	EXPOSURE	SELECTED HIGH-RISK FACTORS	AT-RISK DIAGNOSTIC GROUPS
REPRODUCTIVE			
Gonadal dysfunction Delayed or arrested puberty Premature menopause Germ cell dysfunction or failure Infertility	Chemotherapy, alkylating: • Busulfan • Carmustine (BCNU) • Chlorambucil • Cyclophosphamide • Ifosfamide • Lomustine (CCNU) • Mechlorethamine • Melphalan • Procarbazine Radiation affecting reproductive system: • Whole abdomen (girls) • Pelvic • Lumbar/sacral spine (girls) • Testicular (boys) • TBI	Higher alkylating agent dose Alkylating agent conditioning for HSCT Radiation dose ≥15 Gy in prepubertal girls Radiation dose ≥10 Gy in pubertal girls For germ cell failure in boys, any pelvic irradiation For androgen insufficiency, gonadal irradiation, ≥20-30 Gy in boys	Acute lymphoblastic leukemia, high risk Brain tumor Hodgkin lymphoma, advanced or unfavorable Non-Hodgkin lymphoma, advanced or unfavorable Sarcoma Neuroblastoma Wilms tumor, advanced Autologous or allogeneic HSCT
CARDIAC			
Cardiomyopathy Arrhythmias	Chemotherapy: • Daunorubicin • Doxorubicin • Idarubicin	Female sex Age <5 yr at time of treatment Higher doses of chemotherapy (≥300 mg/m^2) Higher doses of cardiac radiation (≥30 Gy) Combined-modality therapy with cardiotoxic chemotherapy and irradiation	Hodgkin lymphoma Leukemia Non-Hodgkin lymphoma Sarcoma Wilms tumor Neuroblastoma
Cardiomyopathy Arrhythmias Pericardial fibrosis Valvular disease Myocardial infarction Atherosclerotic heart disease	Radiation affecting heart: • Chest • Mantle • Mediastinum • Axilla • Spine • Upper abdomen		
PULMONARY			
Pulmonary fibrosis Interstitial pneumonitis Restrictive lung disease Obstructive lung disease	Chemotherapy: • Bleomycin • Busulfan • Carmustine (BCNU) • Lomustine (CCNU) Radiation impacting lungs: • Mantle • Mediastinum • Whole lung • TBI	Higher doses of chemotherapy Combined modality therapy with pulmonary toxic chemotherapy and irradiation	Brain tumor Germ cell tumor Hodgkin lymphoma Sarcoma (chest wall or intrathoracic) Autologous or allogeneic HCST
GASTROINTESTINAL			
Chronic enterocolitis Strictures Bowel obstruction	Radiation affecting gastrointestinal tract (≥30 Gy) Abdominal surgery	Higher radiation dose to bowel (≥45 Gy) Combined modality therapy with abdominal irradiation and radiomimetic chemotherapy (dactinomycin or anthracyclines) Combined modality therapy with abdominal surgery and irradiation	Sarcoma (retroperitoneal or pelvic primary)
HEPATIC			
Hepatic fibrosis Cirrhosis	Radiation affecting liver	Higher radiation dose or treatment volume (20-30 Gy to entire liver or ≥40 Gy to at least one third of liver)	Sarcoma Neuroblastoma
RENAL			
Renal insufficiency Hypertension Glomerular injury Tubular injury	Chemotherapy: • Ifosfamide • Cisplatin • Carboplatin Radiation affecting kidneys: • Whole abdomen • Upper abdominal fields • TBI		

GH, Growth hormone; HPA, hypothalamic–pituitary–adrenal axis; HSCT, hematopoietic stem cell transplantation; TBI, total-body irradiation.

From Kurt BA, Arnstrong GT, Cash DK, et al: Primary care management of the childhood cancer survivor, J Pediatr 152:458–466, 2008.

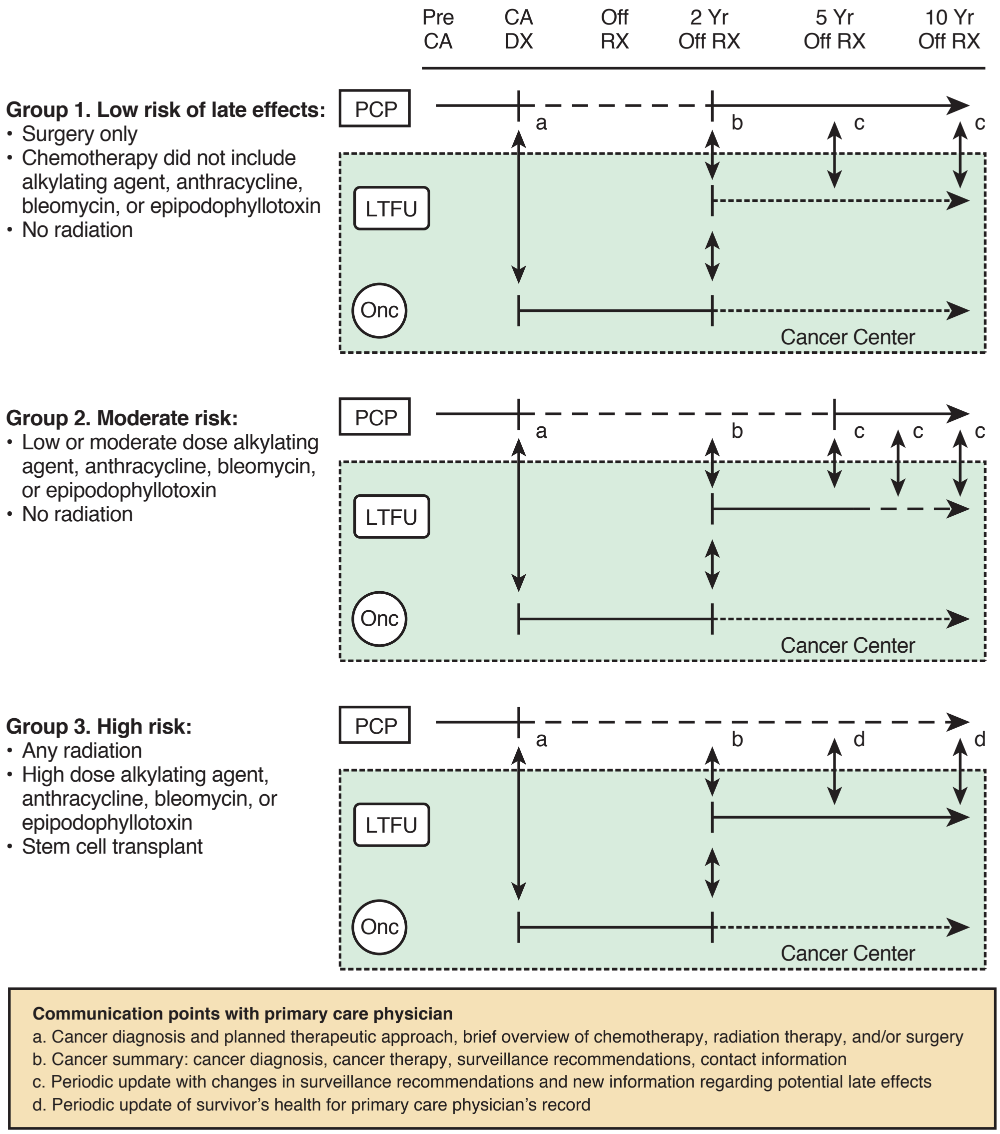

Figure 494-6 Proposed risk-stratified shared care model for childhood cancer survivors. *Solid line* denotes primary responsibility for risk-based care; risk stratification based upon determination of the long-term follow-up staff. *CA*, Cancer; *DX*, diagnosis; *Onc*, oncologist; *PCP*, primary care provider; *RX*, therapy. *(Adapted from Oeffinger KC, McCabe MS. Models for delivering survivorship care,* J Clin Oncol *24(32):5119, 2006; with permission from the American Society of Clinical Oncology. From Oeffinger KC, Nathan PC, Kremer LCM: Challenges after curative treatment for childhood cancer and long-term follow up of survivors,* Pediatr Clin North Am *55:251–273, 2008.)*

doses, cranial irradiation can produce neurologic dysfunction and spinal irradiation can produce growth retardation.

Chemotherapy also carries the risk of long-lasting organ damage. Of particular concern are leukoencephalopathy after high-dose methotrexate therapy; infertility in male patients treated with alkylating agents (e.g., cyclophosphamide); myocardial damage caused by anthracyclines; pulmonary fibrosis caused by bleomycin; renal dysfunction caused by ifosfamide, nitrosourea, or platinum agents; and hearing loss from cisplatin. Development of these sequelae may be dose-related and usually is irreversible. Appropriate baseline and intermittent testing should be performed before these drugs are administered to ensure that there is no preexisting damage to the organs likely to be affected and to permit monitoring of the adverse effects of treatment-induced changes.

Perhaps the most serious late adverse effect is the occurrence of **second cancers** in patients successfully cured of a first malignancy. The risk appears to be cumulative, increasing by approximately 0.5% per year, resulting in approximately a 12% incidence at 25 yr after treatment. Patients who have been treated for childhood cancer should be examined annually, with particular attention to possible late adverse effects of therapy, including second malignancies (Fig. 494-6).

PALLIATIVE CARE

At all stages of caring for children with cancer, principles of palliative care should be applied to relieve pain and suffering and to provide comfort (see Chapter 43). Pain is a serious cause of suffering among patients with cancer. It may be the result of organ obstruction or compression or bone metastasis, or it may be neuropathic. Pain should be managed in a stepwise manner, as recommended by the WHO, in accordance with the principles of selecting the appropriate analgesic, prescribing the appropriate dosage, administering the drug by the appropriate route, and choosing an appropriate dosing schedule to prevent persistent pain and to relieve breakthrough pain (see Chapter 62). In addition, the dosage should be titrated aggressively while attempts are made to prevent, anticipate, and manage side effects. Adjuvant drugs and sequential trials of analgesic drugs should be considered.

The goals in the care of dying patients are to avoid distress for the patient, family, and caregivers; to provide care consistent with the patient's and family's wishes; and to comply with and advocate for clinical, cultural, and ethical standards.

Chapter 495

The Leukemias

David G. Tubergen, Archie Bleyer, A. Kim Ritchey, and Erika Friehling

The leukemias are the most common malignant neoplasms in childhood, accounting for approximately 31% of all malignancies that occur in children younger than 15 yr of age. Each year leukemia is diagnosed in approximately 3,250 children younger than 15 yr of age in the United States, an annual incidence of 4.5 cases per 100,000 children. Acute lymphoblastic leukemia (ALL) accounts for approximately 77% of cases of childhood leukemia, acute myelogenous leukemia (AML) for approximately 11%, chronic myelogenous leukemia (CML) for 2-3%, and juvenile myelomonocytic leukemia (JMML) for 1-2%. The remaining cases consist of a variety of acute and chronic leukemias that do not fit classic definitions for ALL, AML, CML, or JMML.

The leukemias may be defined as a group of malignant diseases in which genetic abnormalities in a hematopoietic cell give rise to an unregulated clonal proliferation of cells. The progeny of these cells have a growth advantage over normal cellular elements, because of their increased rate of proliferation and a decreased rate of spontaneous apoptosis. The result is a disruption of normal marrow function and, ultimately, marrow failure. The clinical features, laboratory findings, and responses to therapy vary depending on the type of leukemia.

495.1 Acute Lymphoblastic Leukemia

Erika Friehling, A. Kim Ritchey, David G. Tubergen, and Archie Bleyer

Childhood ALL was the first disseminated cancer shown to be curable. It actually is a heterogeneous group of malignancies with a number of distinctive genetic abnormalities that result in varying clinical behaviors and responses to therapy.

EPIDEMIOLOGY

ALL is diagnosed in approximately 2,400 children younger than 15 yr of age in the United States each year. ALL has a striking peak incidence at 2-3 yr of age and occurs more in boys than in girls at all ages. This peak age incidence was apparent decades ago in white populations in advanced socioeconomic countries, but it has since been confirmed in the black population of the United States as well. The disease is more common in children with certain chromosomal abnormalities, such as Down syndrome, Bloom syndrome, ataxia-telangiectasia, and Fanconi anemia. Among identical twins, the risk to the second twin if 1 twin develops leukemia is greater than that in the general population. The risk is >70% if ALL is diagnosed in the first twin during the 1st yr of life and the twins shared the same (monochorionic) placenta. If the first twin develops ALL by 5-7 yr of age, the risk to the second twin is at least twice that of the general population, regardless of zygosity.

ETIOLOGY

In virtually all cases, the etiology of ALL is unknown, although several genetic and environmental factors are associated with childhood leukemia (Table 495-1). Most cases of ALL are thought to be caused by postconception somatic mutations in lymphoid cells. However, the identification of the leukemia-specific fusion-gene sequences in archived neonatal blood spots of some children who develop ALL at a later date indicates the importance of in utero events in the initiation of the malignant process in some cases. The long lag period before the onset of the disease in some children, reported to be as long as 14 yr, supports the concept that additional genetic modifications are required for disease expression. Moreover, those same mutations have been found in neonatal blood spots of children who never go on to develop leukemia.

Table 495-1	Factors Predisposing to Childhood Leukemia
GENETIC CONDITIONS	
Down syndrome	
Fanconi anemia	
Bloom syndrome	
Diamond-Blackfan anemia	
Shwachman-Diamond syndrome	
Kostmann syndrome	
Neurofibromatosis type 1	
Ataxia-telangiectasia	
Severe combined immune deficiency	
Paroxysmal nocturnal hemoglobinuria	
Li-Fraumeni syndrome	
ENVIRONMENTAL FACTORS	
Ionizing radiation	
Drugs	
Alkylating agents	
Epipodophyllotoxin	
Benzene exposure	

Exposure to medical diagnostic radiation both in utero and in childhood is associated with an increased incidence of ALL. In addition, published descriptions and investigations of geographic clusters of cases have raised concern that environmental factors can increase the incidence of ALL. Thus far, no such factors other than radiation have been identified in the United States. In certain developing countries, there is an association between B-cell ALL (B-ALL) and Epstein-Barr viral infections.

CELLULAR CLASSIFICATION

The classification of ALL depends on characterizing the malignant cells in the bone marrow to determine the morphology, phenotype as measured by cell membrane markers, and cytogenetic and molecular genetic features. **Morphology** is usually adequate alone to establish a diagnosis, but the other studies are essential for disease classification, which can have a major influence on the prognosis and the choice of appropriate therapy. The current system used is the World Health Organization (WHO) classification of leukemias. Phenotypically, surface markers show that approximately 85% of cases of ALL are classified as B lymphoblastic leukemia (previously termed precursor B-ALL or pre–B-ALL), approximately 15% are T-lymphoblastic leukemia, and approximately 1% are derived from mature B cells. The rare leukemia of mature B cells is termed *Burkitt leukemia* and is one of the most rapidly growing cancers in humans, requiring a different therapeutic approach than other subtypes of ALL. A small percentage of children with leukemia have a disease characterized by surface markers of both lymphoid and myeloid derivation.

Chromosomal abnormalities are used to subclassify ALL into prognostic groups (Table 495-2). Many genetic alterations, including inactivation of tumor-suppressor genes and mutations that activate the *NOTCH1* or *RAS* pathways, have been discovered and might one day be incorporated into clinical practice (Fig. 495-1).

The polymerase chain reaction and fluorescence in situ hybridization techniques offer the ability to pinpoint molecular genetic abnormalities and can be used to detect small numbers of malignant cells at diagnosis as well as during follow-up (**minimal residual disease [MRD]**, see below) and are of proven clinical utility. The development of DNA microanalysis makes it possible to analyze the expression of thousands of genes in the leukemic cell. This technique promises to further enhance the understanding of the fundamental biology and to provide clues to the therapeutic approach of ALL.

CLINICAL MANIFESTATIONS

The initial presentation of ALL usually is nonspecific and relatively brief. Anorexia, fatigue, malaise, and irritability often are present, as is

Table 495-2	Common Chromosomal Abnormalities in Acute Lymphoblastic Leukemia of Childhood			
SUBTYPE	**CHROMOSOMAL ABNORMALITY**	**GENETIC ALTERATION**	**PROGNOSIS**	**INCIDENCE**
B-ALL	Trisomies 4, 10, and 17	—	Favorable	25%
B-ALL	t(12;21)	*ETV6-RUNX1*	Favorable	20-25%
B-ALL	t(1;19)	*E2A-PBX*	None	5-6%
B-ALL	t(4;11)	*MLL-AF4*	Unfavorable	2%
B-ALL	t(9;22)	*BCR-ABL*	Unfavorable	3%
Mature B-cell leukemia (Burkitt)	t(8;14)	*IGH-MYC*	None	1-2%
B-ALL	Hyperdiploidy	—	Favorable	20-25%
B-ALL	Hypodiploidy	—	Unfavorable	1%
T-ALL	t(10;14)	*TLX1/HOX11*	Favorable	5-10%
Infant	11q23	*MLL* rearrangements	Unfavorable	2-10%

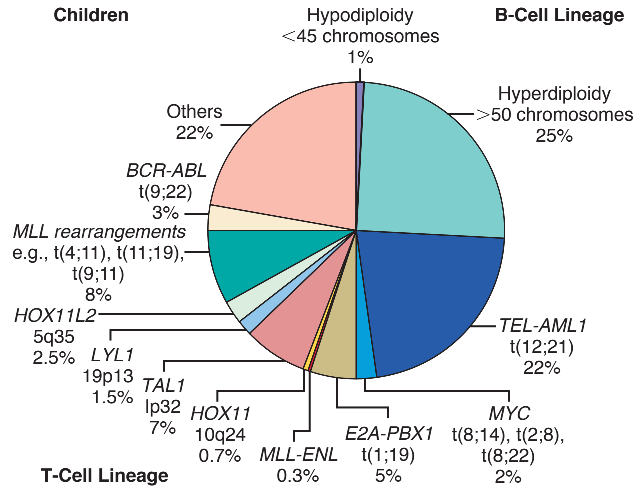

Figure 495-1 Estimated frequency of specific genotypes in childhood ALL. The genetic lesions that are exclusively seen in cases of T-cell ALL are indicated in *gold* and those commonly associated with B-cell ALL in *blue*. The *darker gold* or *blue* color indicates those subtypes generally associated with poor prognosis. *(From Pui CH, Mulligan CG, Evans WE: Pediatric acute lymphoblastic leukemia: where are we going and how do we get there?* Blood *120:1165–1174, 2012.)*

an intermittent, low-grade fever. Bone or joint pain, particularly in the lower extremities, may be present. Less commonly, symptoms may be of several months' duration, may be localized predominantly to the bones or joints, and can include joint swelling. Bone pain is severe and can wake the patient at night. As the disease progresses, signs and symptoms of bone marrow failure become more obvious with the occurrence of pallor, fatigue, exercise intolerance, bruising, or epistaxis, as well as fever, which may be caused by infection or the disease. Organ infiltration can cause lymphadenopathy, hepatosplenomegaly, testicular enlargement, or central nervous system (CNS) involvement (cranial neuropathies, headache, seizures). Respiratory distress may be due to severe anemia or mediastinal node compression of the airways.

On **physical examination,** findings of pallor, listlessness, purpuric and petechial skin lesions, or mucous membrane hemorrhage can reflect bone marrow failure (see Chapter 493). The proliferative nature of the disease may be manifested as lymphadenopathy, splenomegaly, or, less commonly, hepatomegaly. In patients with bone or joint pain, there may be exquisite tenderness over the bone or objective evidence of joint swelling and effusion. Nonetheless, with marrow involvement, deep bone pain may be present but tenderness will not be elicited. Rarely, patients show signs of increased intracranial pressure that indicate leukemic involvement of the CNS. These include papilledema (see Fig. 493-3), retinal hemorrhages, and cranial nerve palsies. Respiratory distress usually is related to anemia but can occur in patients with an obstructive airway problem (wheezing) as the result of a large anterior mediastinal mass (e.g., in the thymus or nodes). This problem is most typically seen in adolescent boys with T-cell ALL (T-ALL). T-ALL also usually has a higher leukocyte count.

B-lymphoblastic leukemia is the most common immunophenotype, with onset at 1-10 yr of age. The median leukocyte count at presentation is 33,000/µL, although 75% of patients have counts <20,000/µL; thrombocytopenia is seen in 75% of patients, and hepatosplenomegaly is seen in 30-40% of patients. In all types of leukemia, CNS symptoms are seen at presentation in 5% of patients (5-10% have blasts in the cerebrospinal fluid [CSF]). Testicular involvement is rarely evident at diagnosis, but prior studies indicate occult involvement in 25% of boys. There is no indication for testicular biopsy.

DIAGNOSIS

The diagnosis of ALL is strongly suggested by peripheral blood findings that indicate bone marrow failure. Anemia and thrombocytopenia are seen in most patients. Leukemic cells might not be reported in the peripheral blood in routine laboratory examinations. Many patients with ALL present with total leukocyte counts of <10,000/µL. In such cases, the leukemic cells often are reported initially to be atypical lymphocytes, and it is only on further evaluation that the cells are found to be part of a malignant clone. When the results of an analysis of peripheral blood suggest the possibility of leukemia, the bone marrow should be examined promptly to establish the diagnosis. It is important that all studies necessary to confirm a diagnosis and adequately classify the type of leukemia be performed, including bone marrow aspiration and biopsy, flow cytometry, cytogenetics, and molecular studies.

ALL is diagnosed by a bone marrow evaluation that demonstrates >25% of the bone marrow cells as a homogeneous population of lymphoblasts. Initial evaluation also includes CSF examination. If lymphoblasts are found and the CSF leukocyte count is elevated, overt CNS or meningeal leukemia is present. This finding reflects a worse stage and indicates the need for additional CNS and systemic therapies. The staging lumbar puncture may be performed in conjunction with the first dose of intrathecal chemotherapy, if the diagnosis of leukemia was previously established from bone marrow evaluation. An experienced proceduralist should perform the initial lumbar puncture, because a traumatic lumbar puncture is associated with an increased risk of CNS relapse.

DIFFERENTIAL DIAGNOSIS

The diagnosis of leukemia is readily made in the patient with typical signs and symptoms, anemia, thrombocytopenia, and elevated white blood count with blasts present on smear. Elevation of the lactate dehydrogenase is often a clue to the diagnosis of ALL. When only pancytopenia is present, aplastic anemia (congenital or acquired) and myelofibrosis should be considered. Failure of a single cell line, as seen in transient erythroblastopenia of childhood, immune thrombocytopenia, and congenital or acquired neutropenia, is rarely the presenting feature of ALL. A high index of suspicion is required to differentiate ALL from infectious mononucleosis in patients with acute onset of fever and lymphadenopathy and from juvenile idiopathic arthritis in patients with fever, bone pain but often no tenderness, and joint swelling. These presentations also can require bone marrow examination.

ALL must be differentiated from AML and other malignant diseases that invade the bone marrow and can have clinical and laboratory findings similar to ALL, including neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, and retinoblastoma.

TREATMENT

The single most important prognostic factor in ALL is the treatment: without effective therapy, the disease is fatal. Considerable progress has been made in event-free survival for children with ALL since the 1970s through use of multiagent chemotherapeutic regimens, intensification of therapy, and selection of treatment based upon relapse risk (Fig. 495-2). Survival is also related to age (Fig. 495-3) and subtype (Fig. 495-4).

Risk-directed therapy has become the standard of current ALL treatment and takes into account age at diagnosis, initial white blood cell count, immunophenotypic and cytogenetic characteristics of blast populations, rapidity of early treatment response (i.e., how quickly the leukemic cells can be cleared from the marrow or peripheral blood),

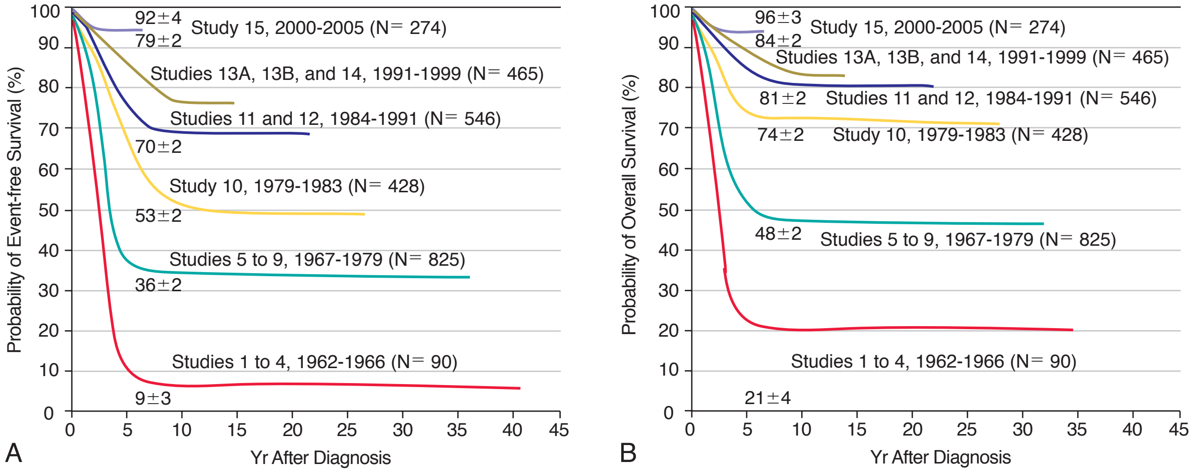

Figure 495-2 **Kaplan-Meier analyses of event-free survival (A) and overall survival (B) in 2,628 children with newly diagnosed ALL.** The patients participated in 15 consecutive studies conducted at St. Jude Children's Research Hospital from 1962-2005. The 5 yr event-free and overall survival estimates (±SE) are shown, except for Study 15, for which preliminary results at 4 yr are provided. The results demonstrate steady improvement in clinical outcome over the past 4 decades. The difference in event-free and overall survival rates has narrowed in the more recent periods, suggesting that relapses or second cancers that occur after contemporary therapy are more refractory to treatment. *(From Pui CH, Evans WE: Treatment of acute lymphoblastic leukemia*, N Engl J Med *354:166–178, 2006.)*

and assessment of MRD at the end of induction therapy. Different study groups use various factors to define risk, but age between 1 and 10 yr old and a leukocyte count of <50,000/µL are used by the National Cancer Institute to define standard risk. Children who are younger than 1 or older than 10 yr of age or who have an initial leukocyte count of >50,000/µL are considered to be high risk. Additional characteristics that adversely affect outcome include T-cell immunophenotype or a slow response to initial therapy. Chromosomal abnormalities, including hypodiploidy, the Philadelphia chromosome, and *MLL* gene rearrangements, portend a poorer outcome. Other mutations, such as in the *IKZF1* gene, have been shown to be associated with a poor prognosis and may become important in treatment algorithms in the future. More favorable characteristics include a rapid response to therapy, hyperdiploidy, trisomy of specific chromosomes (4, 10, and 17), and rearrangements of the *ETV6-RUNX1* (formerly *TEL-AML1*) genes.

The outcome for patients at higher risk can be improved by administration of more intensive therapy despite the greater toxicity of such therapy. Infants with ALL, along with patients who present with specific chromosomal abnormalities, such as t(4;11), have an even higher risk of relapse despite intensive therapy. However, the poor outcome of Philadelphia chromosome positive ALL with t(9;22) has dramatically changed by the addition of imatinib to an intensive chemotherapy backbone. Imatinib is an agent specifically designed to inhibit the BCR-ABL kinase resulting from the translocation. With this new approach, the event-free survival has improved from 30% to 70%. Clinical trials demonstrate that the prognosis for patients with a slower response to initial therapy may be improved by therapy that is more intensive than the therapy considered necessary for patients who respond more rapidly.

Most children with ALL are treated in clinical trials conducted by national or international cooperative groups. Standard treatment involves chemotherapy for 2-3 yr and most achieve remission at the end of the induction phase. Patients in clinical remission can have **MRD** that can only be detected with specific molecular probes to translocations and other DNA markers contained in leukemic cells or specialized flow cytometry. MRD can be quantitative and can provide an estimate of the burden of leukemic cells present in the marrow. Higher levels of MRD present at the end of induction suggest a poorer prognosis and higher risk of subsequent relapse. MRD of >0.01% on the marrow on day 29 of induction is a significant risk factor for shorter event-free survival for all risk categories, when compared with patients with negative MRD. Therapy for ALL intensifies treatment in patients with evidence of MRD at the end of induction.

Initial therapy, termed **remission induction**, is designed to eradicate the leukemic cells from the bone marrow. During this phase, therapy is given for 4 wk and consists of vincristine weekly, a corticosteroid such as dexamethasone or prednisone, and usually a single dose of a long-acting, pegylated asparaginase preparation. Patients at higher risk also receive daunomycin at weekly intervals. With this approach, 98% of patients are in **remission,** as defined by <5% blasts in the marrow and a return of neutrophil and platelet counts to near-normal levels after 4-5 wk of treatment. Intrathecal chemotherapy is always given at the start of treatment and at least once more during induction.

The second phase of treatment, **consolidation**, focuses on intensive **CNS therapy** in combination with continued intensive systemic therapy in an effort to prevent later CNS relapses. Intrathecal chemotherapy is given repeatedly by lumbar puncture. The likelihood of later CNS relapse is thereby reduced to <5%, from historical incidence as high as 60%. A small percentage of patients with features that predict a high risk of CNS relapse may receive irradiation to the brain in later phases of therapy. This includes patients who, at the time of diagnosis, have lymphoblasts in the CSF and either an elevated CSF leukocyte count or physical signs of CNS leukemia, such as cranial nerve palsy.

Subsequently, many regimens provide 14-28 wk of therapy, with the drugs and schedules used varying depending on the risk group of the patient. This period of treatment is often termed **intensification** and includes phases of aggressive treatment **(delayed intensification)** as well as relatively nontoxic phases of treatment (**interim maintenance**). Multiagent chemotherapy, including such medications as cytarabine, methotrexate, asparaginase, and vincristine, is used during these phases to eradicate residual disease.

Finally, patients enter the **maintenance** phase of therapy, which lasts for 2-3 yr, depending on the protocol used. Patients are given daily mercaptopurine and weekly oral methotrexate, usually with intermittent doses of vincristine and a corticosteroid.

A small number of patients with particularly poor prognostic features, such as those with induction failure or extreme hypodiploidy, may undergo bone marrow transplantation during the first remission.

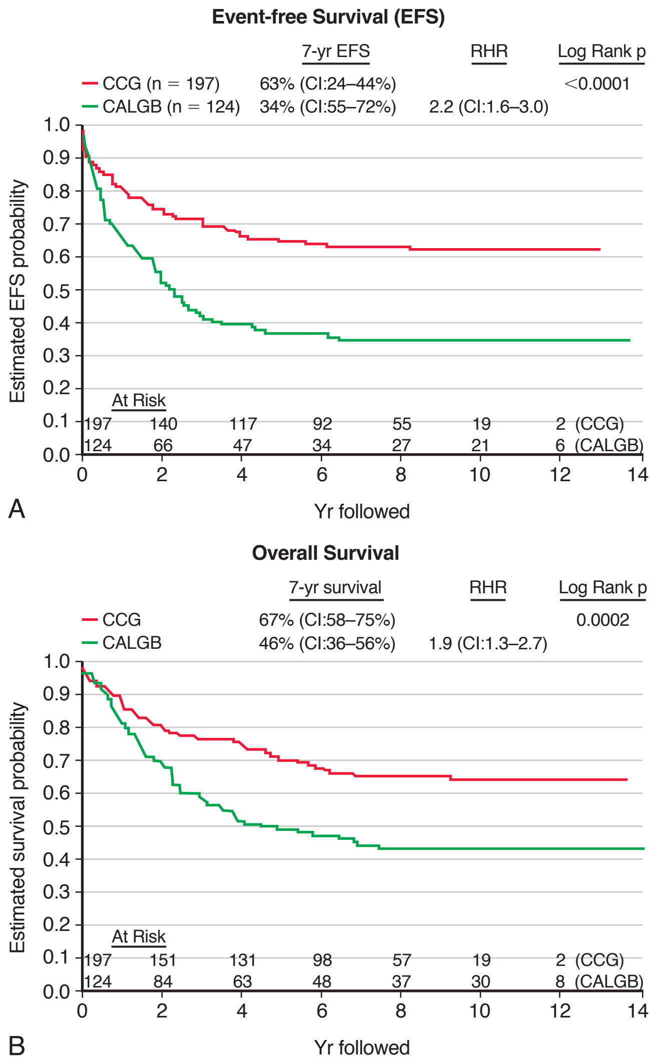

Figure 495-5 Comparison of event-free survival among Cancer and Leukemia Group B (CALGB) (adult protocol, *green line*) and Children's Cancer Group (CCG) (pediatric protocol, *red line*) patients. *(From Stock W, La M, Sanford B, et al: What determines the outcomes for adolescents and young adults with acute lymphoblastic leukemia treated on cooperative group protocols? A comparison of Children's Cancer Group and Cancer and Leukemia Group B studies,* Blood *112: 1646–1654, 2008.)*

Adolescents and young adults with ALL have an inferior prognosis compared to children younger than 15 yr old. They often have adverse prognostic factors and require more intensive therapy. Patients in this age group have a superior outcome when treated with pediatric as opposed to adult treatment protocols (Fig. 495-5). Although the explanation for these findings may be multifactorial, it is important that these patients be treated with pediatric treatment protocols, ideally in a pediatric cancer center.

There are genetic polymorphisms of enzymes important in drug metabolism, which may impact both the efficacy and toxicity of chemotherapeutic medications. **Pharmacogenetic testing** of the thiopurine *S*-methyltransferase *(TPMT)* gene, which encodes one of the metabolizing enzymes of mercaptopurine, can identify patients who are wild type (normal TPMT enzyme activity), heterozygous (slightly decreased TPMT enzyme activity), or homozygous (low or absent enzyme activity). Decreased TPMT enzyme activity results in an accumulation of a toxic metabolite of mercaptopurine and results in severe myelosuppression, requiring dose reductions of the chemotherapy (see Chapter 59). In the future, treatment also may be stratified by gene expression profiles of leukemic cells. In particular, gene expression arrays induced by exposure to a chemotherapeutic agent can predict which patients have drug-resistant ALL.

Treatment of Relapse

The major impediment to a successful outcome is relapse of the disease. Outcomes remain poor among those that relapse, with the most important prognostic indicators being time from diagnosis and the site of relapsed disease. In addition, other factors, such as immunophenotype (T-ALL worse than B-ALL) and age at initial diagnosis, have prognostic significance.

Relapse occurs in the bone marrow in 15-20% of patients with ALL and carries the most serious implications, especially if it occurs during or shortly after completion of therapy. Intensive chemotherapy with agents not previously used in the patient followed by allogeneic stem cell transplantation can result in long-term survival for some patients with bone marrow relapse (see Chapter 135).

The incidence of CNS relapse has decreased to <5% since introduction of preventive CNS therapy. CNS relapse may be discovered at the time of a routine lumbar puncture in the asymptomatic patient. Symptomatic patients with relapse in the CNS usually present with signs and symptoms of increased intracranial pressure and can present with isolated cranial nerve palsies. The diagnosis is confirmed by demonstrating the presence of leukemic cells in the CSF. The treatment includes intrathecal medication and cranial or craniospinal irradiation. Systemic chemotherapy also must be used, because these patients are at high risk for subsequent bone marrow relapse. Most patients with leukemic relapse confined to the CNS do well, especially those in whom the CNS relapse occurs longer than 18 mo after initiation of chemotherapy.

Testicular relapse occurs in less than 2% of boys with ALL, usually after completion of therapy. Such relapse occurs as painless swelling of 1 or both testes. The diagnosis is confirmed by biopsy of the affected testis. Treatment includes systemic chemotherapy and possibly local irradiation. A high proportion of boys with a testicular relapse can be successfully retreated, and the survival rate of these patients is good.

The most current information on treatment of childhood ALL is available in the PDQ (Physician Data Query) on the National Cancer Institute website (http://www.cancer.gov/cancertopics/pdq/treatment/childALL/healthprofessional/).

SUPPORTIVE CARE

Close attention to the medical supportive care needs of the patients is essential in successfully administering aggressive chemotherapeutic programs. Patients with high white blood counts are especially prone to tumor lysis syndrome as therapy is initiated. The kidney failure associated with very high levels of serum uric acid can be prevented or treated with allopurinol or urate oxidase. Chemotherapy often produces severe myelosuppression, which can require erythrocyte and platelet transfusion and which always requires a high index of suspicion and aggressive empiric antimicrobial therapy for sepsis in febrile children with neutropenia. Patients must receive prophylactic treatment for *Pneumocystis jiroveci* pneumonia during chemotherapy and for several months after completing treatment.

The successful therapy of ALL is a direct result of intensive and often toxic treatment. However, such intensive therapy can incur substantial academic, developmental, and psychosocial costs for children with ALL and considerable financial costs and stress for their families. Both long-term and acute toxicity effects can occur. An array of cancer care professionals with training and experience in addressing the myriad of problems that can arise is essential to minimize the complications and achieve an optimal outcome.

PROGNOSIS

Improvements in therapy and risk stratification have resulted in significant increases in survival rates, with current data showing overall 5 yr survival around 90% (Fig. 495-6). However, survivors are more likely to experience significant chronic medical conditions compared to siblings, including musculoskeletal, cardiac, and neurologic conditions. Overall, long-term management following ALL should be

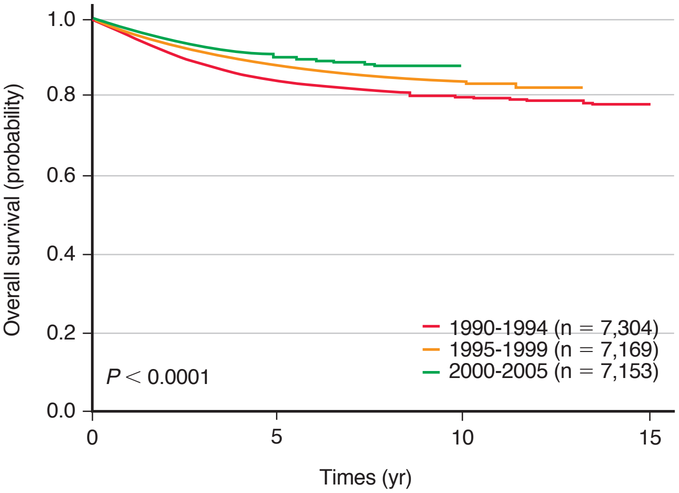

Figure 495-6 Overall survival probabilities by treatment era for patients with ALL enrolled in Children's Oncology Group trials in 1990-1994, 1995-1999, and 2000-2005. *(From Hunger SP, Lu X, Devidas M, et al: Improved survival for children and adolescents with acute lymphoblastic leukemia between 1990 and 2005: A report from the Children's Oncology Group,* J Clin Oncol *30:1663–1669, 2012.)*

conducted in a clinic where children and adolescents can be followed by a variety of specialists to address the challenges of these unique patients.

495.2 Acute Myelogenous Leukemia

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

EPIDEMIOLOGY

AML accounts for 11% of the cases of childhood leukemia in the United States; it is diagnosed in approximately 370 children annually. The relative frequency of AML increases in adolescence, representing 36% of cases of leukemia in 15-19 yr olds. One subtype, acute promyelocytic leukemia (APL), is more common in certain regions of the world, but the incidence of the other types is generally uniform. Several chromosomal abnormalities associated with AML have been identified, but no predisposing genetic or environmental factors can be identified in most patients (see Table 495-1). Nonetheless, a number of risk factors have been identified, including ionizing radiation, chemotherapeutic agents (e.g., alkylating agents, epipodophyllotoxin), organic solvents, paroxysmal nocturnal hemoglobinuria, and certain syndromes: Down syndrome, Fanconi anemia, Bloom syndrome, Kostmann syndrome, Shwachman-Diamond syndrome, Diamond-Blackfan syndrome, Li-Fraumeni syndrome, and neurofibromatosis type 1.

CELLULAR CLASSIFICATION

The characteristic feature of AML is that >20% of bone marrow cells on bone marrow aspiration or biopsy touch preparations constitute a fairly homogeneous population of blast cells, with features similar to those that characterize early differentiation states of the myeloid-monocyte-megakaryocyte series of blood cells. Current practice requires the use of flow cytometry to identify cell surface antigens and use of chromosomal and molecular genetic techniques for additional diagnostic precision and to aid the choice of therapy. The WHO has proposed a new classification system that incorporates morphology, chromosome abnormalities, and specific gene mutations. This system provides significant biologic and prognostic information (Table 495-3).

Table 495-3	WHO Classification of Acute Myeloid Neoplasms

Acute myeloid leukemia with recurrent genetic abnormalities
- AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*
- AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
- APL with t(15;17)(q22;q12); *PML-RARA*
- AML with t(9;11)(p22;q23); *MLLT3-MLL*
- AML with t(6;9)(p23;q34); *DEK-NUP214*
- AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*
- AML (megakaryoblastic) with t(1;22)(p13;q13); *RBM15-MKL1*
- *Provisional entity: AML with mutated NPM1*
- *Provisional entity: AML with mutated CEBPA*

Acute myeloid leukemia with myelodysplasia-related changes
Therapy-related myeloid neoplasms
Acute myeloid leukemia, not otherwise specified
- AML with minimal differentiation
- AML without maturation
- AML with maturation
- Acute myelomonocytic leukemia
- Acute monoblastic/monocytic leukemia
- Acute erythroid leukemia
  - Pure erythroid leukemia
  - Erythroleukemia, erythroid/myeloid
- Acute megakaryoblastic leukemia
- Acute basophilic leukemia
- Acute panmyelosis with myelofibrosis

Myeloid sarcoma
Myeloid proliferations related to Down syndrome
- Transient abnormal myelopoiesis
- Myeloid leukemia associated with Down syndrome

Blastic plasmacytoid dendritic cell neoplasm

AML, acute myelogenous leukemia; APL, acute promyelocytic leukemia.

CLINICAL MANIFESTATIONS

The production of symptoms and signs of AML is a result of replacement of bone marrow by malignant cells and caused by secondary bone marrow failure. Patients with AML can present with any or all of the findings associated with **marrow failure** in ALL. In addition, patients with AML present with signs and symptoms that are uncommon in ALL, including **subcutaneous nodules** or "blueberry muffin" lesions (especially in infants), infiltration of the gingiva (especially in monocytic subtypes), signs and laboratory findings of **disseminated intravascular coagulation** (especially indicative of APL), and discrete masses, known as **chloromas** or **granulocytic sarcomas.** These masses can occur in the absence of apparent bone marrow involvement and typically are associated with a t(8;21) translocation. Chloromas also may be seen in the orbit and epidural space.

DIAGNOSIS

Analysis of bone marrow aspiration and biopsy specimens of patients with AML typically reveals the features of a hypercellular marrow consisting of a monotonous pattern of cells. Flow cytometry and special stains assist in identifying myeloperoxidase-containing cells, thus confirming both the myelogenous origin of the leukemia and the diagnosis. Some chromosomal abnormalities and molecular genetic markers are characteristic of specific subtypes of disease (Table 495-4).

PROGNOSIS AND TREATMENT

Aggressive multiagent chemotherapy is successful in inducing remission in approximately 85-90% of patients. Survival has increased dramatically since the 1970s, when only 15% of newly diagnosed patients survived, compared to a current survival rate of 60-70% with modern therapy (Fig. 495-7). Targeting therapy to genetic markers may be beneficial (see Table 495-4). Up to 5% of patients die of either infection or bleeding before a remission can be achieved. Matched-sibling bone marrow or stem cell transplantation after remission achieves long-term disease-free survival in about two thirds of patients. Continued chemotherapy for patients who do not have a matched sibling donor is

generally less effective than marrow transplantation, but nevertheless is curative in about half of patients. However, for selected patients with favorable prognostic features [t(8;21); t(15;17); inv(16); APL] and improved outcome with chemotherapy, matched sibling stem cell transplantation is recommended only after a relapse. Matched unrelated donor stem cell transplants may be effective therapy, but they carry the risk of significant graft-vs-host disease as well as the complications associated with intensive myeloablative therapy. Matched unrelated donor transplants are usually reserved for patients who have a relapse. However, patients with unfavorable prognostic features (e.g., monosomies 7 and 5, 5q–, and 11q23 abnormalities) who have inferior outcome with chemotherapy might benefit from matched unrelated donor stem cell transplant in first remission.

APL, characterized by a gene rearrangement involving the retinoic acid receptor [t(15;17); PML-RARA], is very responsive to **all-*trans*-retinoic acid (ATRA, tretinoin)** combined with anthracyclines and cytarabine. The success of this therapy makes marrow transplantation in first remission unnecessary for patients with this disease. Arsenic trioxide is an effective noncytotoxic therapy for APL. Data from trials in adults show promising results with the use of combined ATRA/arsenic without cytotoxic drugs as initial therapy for APL and would support a new trial of this regimen in children.

Increased supportive care is needed in patients with AML because the intensive therapy they receive produces prolonged bone marrow suppression with a very high incidence of serious infections, especially *Streptococcal viridans* sepsis and fungal infection. These patients may require prolonged hospitalization, filgrastim (granulocyte colony-stimulating factor), and prophylactic antimicrobials.

The most current information on treatment of AML is available in the PDQ (Physician Data Query) on the National Cancer Institute website (http://www.cancer.gov/cancertopics/pdq/treatment/childAML/healthprofessional/).

495.3 Down Syndrome and Acute Leukemia and Transient Myeloproliferative Disorder

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

Acute leukemia occurs about 15-20 times more frequently in children with Down syndrome than in the general population (see Chapters 81 and 492). The ratio of ALL to AML in patients with Down syndrome is the same as that in the general population. The exception is during the 1st 3 yr of life, when AML is more common. In children with Down syndrome who have ALL, the expected outcome of treatment is slightly inferior to that for other children, which can be partially explained by a lack of good prognostic characteristics, such as *ETV6-RUNX1* and trisomies, as well as genetic abnormalities that are associated with an inferior prognosis, such as *IKZF1*. Patients with Down syndrome demonstrate a remarkable sensitivity to methotrexate and other antimetabolites, which can result in substantial toxicity if standard doses are administered. In AML, however, patients with Down syndrome have much better outcomes than non–Down syndrome children, with a >80% long-term survival rate. After induction therapy, these patients receive therapy that is less intensive to achieve better results.

Approximately 10% of neonates with Down syndrome develop a transient leukemia or **myeloproliferative disorder** characterized by high leukocyte counts, blast cells in the peripheral blood, and associated anemia, thrombocytopenia, and hepatosplenomegaly. These features usually resolve within the 1st 3 mo of life. Although these neonates can require temporary transfusion support, they do not require chemotherapy unless there is evidence of life-threatening complications. However, patients who have Down syndrome and who develop this transient leukemia or myeloproliferative disorder require close follow-up, because 20-30% will develop typical leukemia (often acute megakaryocytic leukemia) by 3 yr of life (mean onset, 16 mo). *GATA1* mutations (a transcription factor that controls megakaryopoiesis) are present in blasts from patients with Down syndrome who have

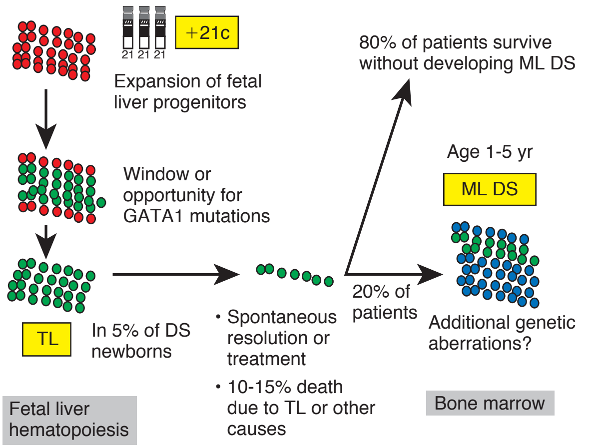

Figure 495-8 Stepwise development of myeloid leukemia in Down syndrome (ML DS) following transient leukemia (TL). TL arises from expanded fetal liver progenitors as a result of constitutional trisomy 21, providing a window of opportunity for the occurrence of acquired mutations in the hematopoietic transcription factor GATA1. In most cases TL spontaneously disappears, but some children need treatment because of severe TL-related symptoms. Approximately 20% of children with TL subsequently develop ML DS, which requires additional hits. *(From Zwaan MC, Reinhardt D, Hitzler J, Vyas P: Acute leukemias in children with Down syndrome,* Pediatr Clin North Am *55:53–70, 2008.)*

transient myeloproliferative disease and also in those with leukemia (Fig. 495-8). Transient myeloproliferative disease also can occur in patients who do not have phenotypic features of Down syndrome. Blasts from these patients might have trisomy 21, suggesting a mosaic state.

Bibliography is available at Expert Consult.

495.4 Chronic Myelogenous Leukemia

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

CML is a clonal disorder of the hematopoietic tissue that accounts for 2-3% of all cases of childhood leukemia. Approximately 99% of the cases are characterized by a specific translocation, t(9;22)(q34;q11), known as the **Philadelphia chromosome,** resulting in a *BCR-ABL* fusion protein.

The presenting symptoms of CML are nonspecific and can include fever, fatigue, weight loss, and anorexia. Splenomegaly also may be present, resulting in pain in the left upper quadrant of the abdomen. The diagnosis is suggested by a high white blood cell count with myeloid cells at all stages of differentiation in the peripheral blood and bone marrow and is confirmed by cytogenetic and molecular studies that demonstrate the presence of the characteristic Philadelphia chromosome and the *BCR-ABL* gene rearrangement. This translocation, although characteristic of CML, is also found in a small percentage of patients with ALL.

The disease is characterized by an initial chronic phase in which the malignant clone produces an elevated leukocyte count with a predominance of mature forms but with increased numbers of immature granulocytes. In addition to leukocytosis, blood counts can reveal mild anemia and thrombocytosis. Typically, the chronic phase terminates 3-4 yr after onset, when the CML moves into the accelerated or "blast crisis" phase. At this point, the blood counts rise dramatically and the clinical picture is indistinguishable from acute leukemia. Additional manifestations can occur, including neurologic symptoms from hyperleukocytosis, which causes increased blood viscosity with decreased CNS perfusion.

Imatinib (Gleevec), an agent designed specifically to inhibit the *BCR-ABL* tyrosine kinase, has been used in adults and children and has shown an ability to produce major cytogenetic responses in >70% of patients (see Table 494-1). Experience in children suggests it can be used safely with results comparable to those seen in adults. Second-generation tyrosine kinase inhibitors, such as **dasatinib**, have improved remission rates in adults and are now included in the first-line therapy in that population while they are being studied in children. While waiting for a response to the tyrosine kinase inhibitor, disabling or threatening signs and symptoms of CML can be controlled during the chronic phase with hydroxyurea, which gradually returns the leukocyte count to normal. Prolonged morphologic and cytogenetic responses are expected, but the opportunity for cure is enhanced by human leukocyte antigen–matched family donor allogeneic stem cell transplant, with up to 80% of children achieving a cure.

Bibliography is available at Expert Consult.

495.5 Juvenile Myelomonocytic Leukemia

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

JMML, formerly termed **juvenile CML,** is a clonal proliferation of hematopoietic stem cells that typically affects children younger than 2 yr of age. JMML is rare, constituting <1% of all cases of childhood leukemia. Patients with this disease do not have the Philadelphia chromosome that is characteristic of CML. Patients with JMML present with rashes, lymphadenopathy, splenomegaly, and hemorrhagic manifestations. Analysis of the peripheral blood often shows an elevated leukocyte count with increased monocytes, thrombocytopenia, and anemia with the presence of erythroblasts. The bone marrow shows a myelodysplastic pattern, with blasts accounting for <20% of cells. Most patients with JMML have been found to have mutations that lead to activation of the *RAS* oncogene pathway including *NF1* and *PTPN11*. Patients with neurofibromatosis type 1 and Noonan syndrome have a predilection for this type of leukemia, since they have germline mutations involved in *RAS* signaling. Therapeutic reports are largely anecdotal. Stem cell transplantation offers the best opportunity for cure but much less so than for classic CML.

Bibliography is available at Expert Consult.

495.6 Infant Leukemia

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

Approximately 2% of cases of leukemia during childhood occur before the age of 1 year. In contrast to older children, the ratio of ALL to AML is 2 : 1. Leukemic clones have been noted in cord blood at birth before symptoms appear, and in 1 case the same clone was noted in maternal cells (maternal to fetal transmission). Chromosome translocations can also occur in utero during fetal hematopoiesis, thus leading to malignant clone formation.

Several unique biologic features and a particularly poor prognosis are characteristic of ALL during infancy. More than 80% of the cases demonstrate rearrangements of the *MLL* gene, found at the site of the 11q23 band translocation, the majority of which are the t(4;11). This subset of patients largely accounts for the very high relapse rate. These patients often present with hyperleukocytosis and extensive tissue infiltration producing organomegaly, including CNS disease. Subcutaneous nodules, known as **leukemia cutis,** and tachypnea caused by diffuse pulmonary infiltration by leukemic cells are observed more often in infants than in older children. The leukemic cell morphology is usually that of large irregular lymphoblasts, with a phenotype

negative for the CD10 (common ALL antigen) marker (pro-B) unlike most older children with B-ALL who are CD10+.

Very intensive chemotherapy programs, including stem cell transplantation, are being explored in infants with *MLL* gene rearrangements, but none has yet proved satisfactory. Infants with leukemia who lack the 11q23 rearrangements have a prognosis similar to that of older children with ALL.

Infants with AML often present with CNS or skin involvement and have a subtype known as **acute myelomonocytic leukemia.** The treatment may be the same as that for older children with AML, with similar outcome. Meticulous supportive care is necessary because of the young age and aggressive therapy needed in these patients.

Chapter 496
Lymphoma

Jessica Hochberg, Lisa Giulino-Roth, and Mitchell S. Cairo

Lymphoma is the third most common cancer among U.S. children (age 14 yr or younger), with an annual incidence of 15 cases per 1 million children. It is the most common cancer in adolescents, accounting for >25% of newly diagnosed cancers in persons 15-19 yr old. The 2 broad categories of lymphoma, Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL), have different clinical manifestations and treatments.*

496.1 Hodgkin Lymphoma

Jessica Hochberg, Lisa Giulino-Roth, and Mitchell S. Cairo

Hodgkin lymphoma (HL) is a malignant process involving the lymphoreticular system that accounts for 6% of childhood cancers. In the United States, HL accounts for approximately 5% of cancers in persons 14 yr of age or younger; it accounts for approximately 15% of cancers in adolescents (15-19 yr of age), making HL the most common malignancy in this age group.

EPIDEMIOLOGY

The worldwide incidence of HL is approximately 2-4 new cases/100,000 population/yr; there is a bimodal age distribution, with peaks at 15-35 yr of age and again after 50 yr. It is the most common cancer seen in adolescents and young adults, and the third most common in children younger than the age of 15 yr. In developing countries, the early peak tends to occur prior to adolescence. A male : female predominance is found among young children, but lessens with age. Infectious agents may be involved, such as human herpesvirus 6, cytomegalovirus, and **Epstein-Barr virus (EBV)**. The role of EBV is supported by prospective serologic studies. Infection with EBV confers a 4-fold higher risk of developing HL and may precede the diagnosis by years. EBV antigens have been demonstrated in HL tissues, particularly type II latent membrane proteins 1 and 2, although EBV status is not thought to be prognostic of outcome.

PATHOGENESIS

The **Reed-Sternberg (RS) cell,** a pathognomonic feature of HL, is a large cell (15-45 µm in diameter) with multiple or multilobulated nuclei. This cell type is considered the hallmark of HL, although similar cells are seen in infectious mononucleosis, NHL, and other conditions. The RS cell is clonal in origin and arises from the germinal center B cells but typically has lost most B-cell gene expression and function. There is no single simple genetic aberration that leads to malignant transformation of the RS cell, but rather a combination of somatic mutations, chromosomal instability, and complex chromosomal rearrangements have been reported with no particular pattern or frequency. This typically leads to cell regulation defects such as constitutive activation of the nuclear factor-κB pathway or abnormal regulation of the Bcl-2 family of proteins. HL is characterized by a variable number of RS cells surrounded by an inflammatory infiltrate of lymphocytes, plasma cells, and eosinophils in different proportions, depending on the HL histologic subtype. The interaction between the RS cell and these background inflammatory cells with their associated cytokine release is important in the development and progression of HL. Reactive infiltration of eosinophils and CD68+ macrophages, and increased concentrations of cytokines, such as interleukins 1 and 6 and tumor necrosis factor, are all associated with an unfavorable prognosis, including advanced stage, the presence of "B" symptoms, decreased response to therapy, and reduced survival. In addition, evidence of CD8+ T cells surrounding the RS cell offers evidence of an important role in T-cell promotion of malignant cell survival, perhaps through the CD30 and CD40 ligands found on RS cells. Other features that distinguish the histologic subtypes include various degrees of fibrosis and the presence of collagen bands, necrosis, or malignant reticular cells (Fig. 496-1). The distribution of subtypes varies with age.

The **Revised World Health Organization Classification of Lymphoid Neoplasms** (Table 496-1) includes 2 modifications of the older Rye system. HL appears to arise in lymphoid tissue and spread to adjacent lymph node areas in a relatively orderly fashion. Hematogenous spread also occurs, leading to involvement of the liver, spleen, bone, bone marrow, or brain, and is usually associated with systemic symptoms.

CLINICAL MANIFESTATIONS

Patients commonly present with painless, nontender, firm, rubbery, cervical or supraclavicular lymphadenopathy and usually some degree of mediastinal involvement. Clinically detectable hepatosplenomegaly is rarely encountered. Depending on the extent and location of nodal and extranodal disease, patients may present with symptoms and signs of airway obstruction (dyspnea, hypoxia, cough), pleural or pericardial effusion, hepatocellular dysfunction, or bone marrow infiltration (anemia, neutropenia, or thrombocytopenia). Disease manifesting below the diaphragm is rare and occurs in approximately 3% of all cases. Systemic symptoms**,** classified as **B symptoms** that are considered important in staging, are unexplained fever >38°C (100.4°F), weight loss >10% total body weight over 6 mo, and drenching night sweats. Less common and not considered of prognostic significance are symptoms of pruritus, lethargy, anorexia, or pain that worsens after ingestion of alcohol. Patients also exhibit immune system abnormalities that often persist during and after therapy.

DIAGNOSIS

Any patient with persistent, unexplained lymphadenopathy unassociated with an obvious underlying inflammatory or infectious process should undergo chest radiography to identify the presence of a large mediastinal mass before undergoing lymph node biopsy. Formal excisional biopsy is preferred over needle biopsy to ensure that adequate tissue is obtained, both for light microscopy and for appropriate immunohistochemical and molecular studies. Once the diagnosis of HL is established, extent of disease (stage) should be determined to allow selection of appropriate therapy (Table 496-2). Evaluation includes history, physical examination, and imaging studies, including chest radiograph; CT scans of the neck, chest, abdomen, and pelvis; and positron emission tomography (PET) scan. Laboratory studies should include a complete blood cell count to identify abnormalities that might suggest marrow involvement; erythrocyte sedimentation rate; and measurement of serum ferritin, which is of some prognostic

From Harris NL, Jaffe ES, Diebold J, et al: The World Health Organization classification of neoplastic diseases of the haematopoietic and lymphoid tissues: report of the Clinical Advisory Committee Meeting, Airlie House, Virginia, November 1997, Histopathology *36:69–87, 2000.*

significance and, if abnormal at diagnosis, serves as a baseline to evaluate the effects of treatment. A chest radiograph is particularly important for measuring the size of the mediastinal mass in relation to the maximal diameter of the thorax (Fig. 496-2). This determines "bulk" disease and becomes prognostically significant. Chest CT more clearly defines the extent of a mediastinal mass if present and identifies hilar nodes and pulmonary parenchymal involvement, which may not be evident on chest radiographs. Bone marrow aspiration and biopsy should be performed to rule out advanced disease. Bone scans are performed in patients with bone pain and/or elevation of alkaline phosphatase. Gallium scan can be particularly helpful in identifying areas of increased uptake, which can then be reevaluated at the end of treatment. Fluorodeoxyglucose PET imaging has advantages over gallium scanning, as it is a 1-day procedure with higher resolution, better dosimetry, less intestinal activity, and the potential to quantify disease. PET scans are being evaluated as a prognostic tool in HL, enabling therapy to be reduced in those predicted to have a good outcome.

The staging classification currently used for HL was adopted at the **Ann Arbor Conference** in 1971 and was revised in 1989 (see Table 496-2). HL can be subclassified into A or B categories: *A* is used to

Table 496-2 Ann Arbor Staging Classification for Hodgkin Lymphoma*

STAGE	DEFINITION
I	Involvement of a single lymph node (I) or of a single extralymphatic organ or site (IE)
II	Involvement of 2 or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and 1 or more lymph node regions on the same side of the diaphragm (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may be accompanied by involvement of the spleen (IIIS) or by localized involvement of an extralymphatic organ or site (IIIE) or both (IIISE)
IV	Diffuse or disseminated involvement of 1 or more extralymphatic organs or tissues with or without associated lymph node involvement

*The absence or presence of fever >38°C (100.4°F) for 3 consecutive days, drenching night sweats, or unexplained loss of >10% of body weight in the 6 mo preceding admission are to be denoted in all cases by the suffix letter A or B, respectively.

From Lister TA, Crowther D, Sutcliffe SB, et al: Report of a committee convened to discuss the evaluation and staging of patients with Hodgkin's disease: Cotswolds meeting, J Clin Oncol *7:1630–1636, 1989.*

identify asymptomatic patients and *B* is for patients who exhibit any B symptoms. Extralymphatic disease resulting from direct extension of an involved lymph node region is designated by category E. A complete response in HL is defined as the complete resolution of disease on clinical examination and imaging studies or at least 70-80% reduction of disease and a change from initial positivity to negativity on either gallium or PET scanning because residual fibrosis is common.

TREATMENT

Multiple agents allow different mechanisms of action to have nonoverlapping toxicities so that full doses can be given to each patient.

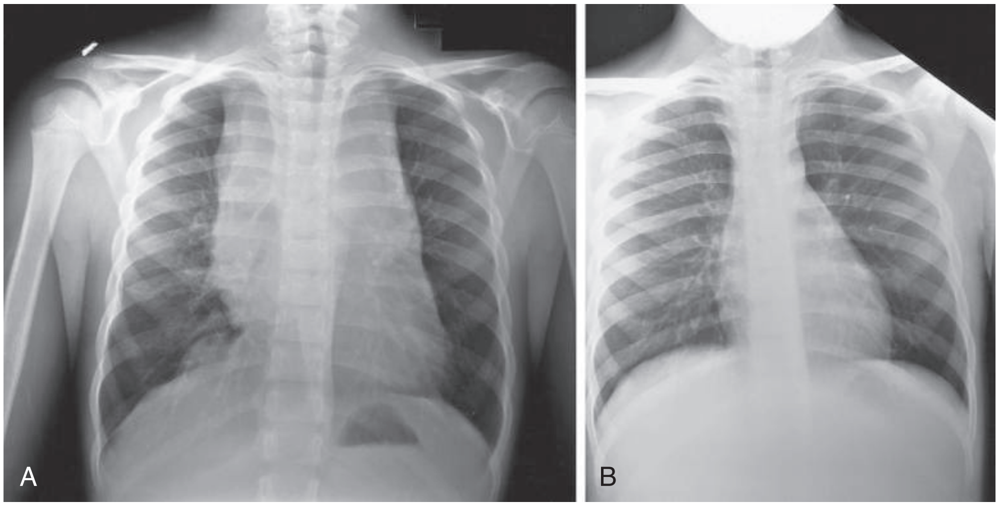

Figure 496-2 **A,** Anterior mediastinal mass in a patient with Hodgkin disease before therapy. **B,** After 2 mo of chemotherapy, the mediastinal mass has disappeared.

Chemotherapy and radiation therapy are both effective in the treatment of HL. Treatment of HL in pediatric patients is risk adapted and involves the use of combined chemotherapy with or without low-dose involved-field radiation therapy based on response. Treatment is determined largely by disease stage, presence or absence of B symptoms, and the presence of bulky nodal disease. Radiation therapy alone, once given at higher doses, initially resulted in prolonged remission and cure rates in patients with low-stage HL. However, this treatment also caused significant long-term morbidity in pediatric patients, including growth retardation, thyroid dysfunction, and cardiac and pulmonary toxicity. The development of effective multiagent combination chemotherapy was a major milestone in the treatment of HL resulting in a complete response rate of 70-80% and cure rate of 40-50% in patients with advanced-stage disease. However, this regimen also led to significant acute and long-term toxicity. The desire to reduce side effects and morbidity has stimulated attempts to reduce the intensity of chemotherapy as well as radiation dose and volume. Newer combinations of chemotherapy have reduced the risk of secondary cancers. Also, current radiation therapy utilizes lower amounts of overall radiation in addition to narrowing the radiation treatment field to either involved-field or even involved-node irradiation. The current Children's Oncology Group trials are investigating whether radiation therapy can be eliminated altogether in patients who have a very good rapid early response to pre-radiation induction chemotherapy.

Chemotherapy agents commonly used to treat children and adolescents with HL include cyclophosphamide, procarbazine, vincristine or vinblastine, prednisone or dexamethasone, doxorubicin, bleomycin, dacarbazine, etoposide, methotrexate, and cytosine arabinoside. The combination chemotherapy regimens in current use are based on **COPP** (cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisone) or **ABVD** (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine), with the addition of prednisone, cyclophosphamide, and etoposide (**ABVE-PC** and **BEACOPP**) or **BAVD** (brentuximab vedotin, doxorubicin [Adriamycin], vincristine, dacarbazine) in various combinations for intermediate- and high-risk groups (Table 496-3). "Risk-adapted" protocols are based on both staging criteria and rapidity of response to initial chemotherapy. The aim is to reduce total drug doses and treatment duration and to eliminate radiation therapy if possible.

Agents such as those that disrupt the nuclear factor-κB pathway or monoclonal antibodies that target RS tumor cells as well as the benign reactive cells that surround them are currently being investigated. Ongoing clinical trials report encouraging results with the use of anti-CD20 antibody (rituximab), particularly in nodular lymphocyte-predominant Hodgkin lymphoma where trials in relapsed disease have shown an overall response rate of 94%. In addition, anti-CD30 agents

Table 496-3 Chemotherapy Regimens Commonly Used for Children, Adolescents, and Young Adults with Hodgkin Lymphoma

CHEMOTHERAPY REGIMEN	CORRESPONDING AGENTS
ABVD	Doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine
ABVD-Rituxan	Doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine, rituximab
ABVD	Doxorubicin (Adriamycin), brentuximab, vinblastine, dacarbazine
ABVE (DBVE)	Doxorubicin (Adriamycin), bleomycin, vincristine, etoposide
VAMP	Vincristine, doxorubicin (Adriamycin), methotrexate, prednisone
OPPA ± COPP (females)	Vincristine (Oncovin), prednisone, procarbazine, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine
OEPA ± COPP (males)	Vincristine (Oncovin), etoposide, prednisone, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine
COPP/ABV	Cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine, doxorubicin (Adriamycin), bleomycin, vinblastine
BEACOPP (advanced stage)	Bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine
COPP	Cyclophosphamide, vincristine (Oncovin), prednisone, procarbazine
CHOP	Cyclophosphamide, doxorubicin (Adriamycin), vincristine (Oncovin), prednisone
ABVE-PC (DBVE-PC)	Doxorubicin (Adriamycin), bleomycin, vincristine, etoposide, prednisone, cyclophosphamide
ICE ± (Brentuximab)	Ifosfamide, carboplatin, etoposide ± brentuximab
Ifos/Vino ± (Brentuximab)	Ifosfamide, vinorelbine ± brentuximab

are being used that are targeted to the RS cells themselves, where CD30 is abundantly expressed. Brentuximab vedotin is an antibody–drug conjugate that is now FDA approved to treat Hodgkin lymphoma. It combines the chimeric anti-CD30 antibody brentuximab linked to the antimitotic agent monomethyl auristatin E. This agent shows impressive efficacy as single-agent therapy in refractory HL and is currently being tested as part of upfront therapy combined with chemotherapy in patients with newly diagnosed disease. EBV-specific cytotoxic T lymphocytes (CTLs) can also be generated from allogeneic donors for patients with advanced HL (Fig. 496-3). In clinical trials, these show promising results, with enhanced antiviral activity and stabilization of disease even though all patients continue to have persistent disease. EBV-CTLs have been developed and are currently being investigated. These enhanced EBV-CTLs are designed to be latent membrane protein 1/2 specific and can be generated from second (in the case of bone marrow transplant recipients) or even third-party donors for patients with refractory disease. These newer approaches represent an exciting new direction in adoptive cellular tumor immunology, and it remains to be determined whether CTLs will have improved cytotoxicity that can overcome inhibitory signals.

RELAPSE

Most relapses occur within the 1st 3 yr after diagnosis, but relapses as late as 10 yr have been reported. Relapse cannot be predicted accurately with this disease. Poor prognostic features include tumor bulk, stage at diagnosis, extralymphatic disease, and presence of B symptoms. Patients who achieve an initial chemosensitive response but relapse or progress less than 12 mo from diagnosis are candidates for myeloablative chemotherapy and autologous stem cell transplantation with or without the addition of radiation therapy. Retrospective studies show a significant decrease in relapse in patients with HL following allogeneic vs autologous stem cell transplant (18% vs 41%). Although in earlier studies there was no improvement in overall survival owing to a high transplantation-related mortality, reduced-intensity conditioning or nonmyeloablative regimens are successful at reducing regimen-related morbidity and mortality associated with myeloablative allogeneic stem cell transplantation while still achieving a strong graft-versus-HL effect. For more difficult-to-treat refractory cases, agents such as Zevalin or Bexxar are being trialed, often in combination with stem cell transplantation strategies. Both are monoclonal anti-CD20 antibodies to which a radioactive isotope is directly linked. Clinical trials show each to be more effective than rituximab in NHL patients, and there is some interest in studying their use in the CD20 subpopulation of HL patients.

PROGNOSIS

With the use of current therapeutic regimens, patients with favorable prognostic factors and early-stage disease have an event-free survival (EFS) of 85-90% and an overall survival (OS) at 5 yr of >95%. Patients with advanced-stage disease have slightly lower EFS (80-85%) and OS (90%), respectively, although OS has approached 100% with dose-intense chemotherapy (Table 496-4). Prognosis after relapse depends

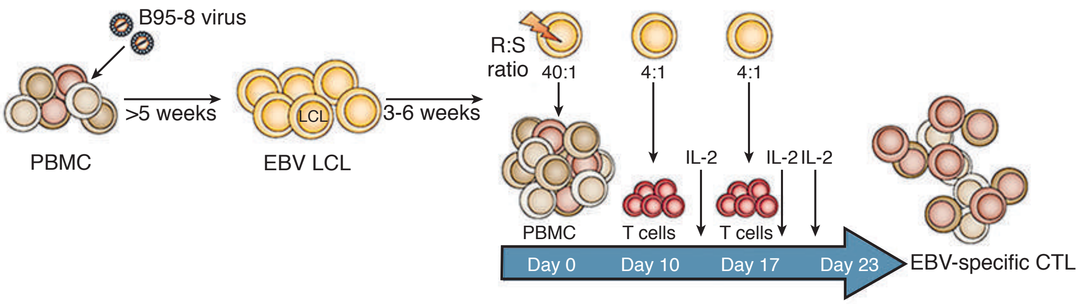

Figure 496-3 **Epstein-Barr virus (EBV)–specific cytotoxic T lymphocyte (CTL) production.** EBV-transformed B-cell lymphoblastoid cell line (LCLs) are prepared from the CTL donor by infection of peripheral blood mononuclear cells (PBMCs) with a clinical-grade laboratory strain of EBV (B95-8) in the presence of cyclosporine. Once the LCL is established (about 6 wk), it is irradiated and used to stimulate PBMCs from the same donor at a 40:1 ratio of PBMC:LCL. From 9-12 days later and weekly thereafter, the T cells are restimulated with the LCL at a 4:1 ratio. Interleukin 2 is added 3 days after the second stimulation and twice weekly thereafter. The CTLs should kill autologous LCLs but not autologous phytohemagglutinin blasts. Their specificity is donor dependent and they may have specificity for any of the 10 latency-associated antigens and/or for early lytic cycle proteins that are expressed by a small fraction of the LCLs, which are grown in acyclovir to prevent the production of infectious virus by blocking the viral thymidine kinase. *(Adapted from Bollard CM, Rooney CM, Heslop HE. T-cell therapy in the treatment of post-transplant lymphoproliferative disease. Nat Rev Clin Oncol 9:510–519, 2012, Fig. 2.)*

on the time from completion of treatment to recurrence, site of relapse (nodal vs extranodal), and presence of B symptoms at relapse. Patients whose disease relapses >12 mo after chemotherapy alone or combined-modality therapy have the best prognosis, and their relapses usually respond to additional standard therapy, resulting in a long-term survival of 60-70%. A myeloablative autologous stem cell transplantation in patients with refractory disease or relapse within 12 mo of therapy results in a long-term survival rate of only 40-50%. Allogeneic stem cell transplantation has shown promise in patients with poor risk features at relapse/progression.

Bibliography is available at Expert Consult.

496.2 Non-Hodgkin Lymphoma

Jessica Hochberg, Lisa Giulino-Roth, and Mitchell S. Cairo

Non-Hodgkin lymphoma (NHL) accounts for approximately 60% of lymphomas in children and is the second most common malignancy in patients age 15-35 yr. The annual incidence of pediatric NHL in the United States is 750-800 cases/yr. In contrast to adult NHL, which is typically indolent, pediatric NHL is usually high grade and aggressive. Although more than 70% of patients present with advanced disease, the prognosis has improved dramatically, with survival rates of 90-95% for localized disease and 70-95% with advanced disease.

EPIDEMIOLOGY

Although most children and adolescents with NHL present with de novo disease, a small number of patients have NHL secondary to specific etiologies, including inherited or acquired immune deficiencies (e.g., severe combined immunodeficiency syndrome, Wiskott-Aldrich syndrome), viruses (e.g., HIV, EBV), and as part of genetic syndromes (e.g., ataxia-telangiectasia, Bloom syndrome). However most children in North America and Europe in whom NHL develops have no obvious genetic or environmental etiology.

PATHOGENESIS

The 4 major pathologic subtypes of childhood and adolescent NHL are **lymphoblastic lymphoma (LBL), Burkitt lymphoma (BL), diffuse large B-cell lymphoma (DLBCL),** and **anaplastic large cell**

lymphoma (**ALCL**; Figs. 496-4 and 496-5). LBL arises from immature B or T lymphocytes whereas BL, DLBCL, and ALCL are mature B- or T-cell neoplasms. DLBCL is further divided into several subtypes: the germinal center B-cell–like, which carries a favorable prognosis and accounts for the vast majority of pediatric cases of DLBCL, and the subtypes with poorer prognosis, activated B-cell–like and primary mediastinal B-cell subtypes. The cell of origin varies among NHL histologic subtypes. Almost all BLs and DLBCLs are of B-cell origin; 90% cases of LBL are of T-cell origin and 10% of B-cell origin; and 70% of cases of ALCL are of T-cell origin, 20% are of null-cell origin, and 10% are of B-cell origin. Cellular surface markers can aid in differentiating NHL subtypes and also present opportunities for targeted treatments. BL and DLBCL frequently express the B-cell antigens CD19, CD20, and CD22. ALCL, in contrast, expresses the CD30 antigen. Some pathologic subtypes have specific cytogenetic aberrations. Children with BL commonly have a t(8;14) translocation (90%) or, less commonly, a t(2;8) or t(8;22) translocation (10%). Children with BL who have a 13q deletion or complex karyotype have a poor prognosis. Those with DLBCL may have a t(8;14) translocation (30%) and often have a complex (80%) and aneuploid (80%) karyotype. Patients with ALCL commonly have a t(2;5) translocation (90%), which results in the formation of a fusion gene encoding the constitutively active nucleophosmin-anaplastic lymphoma kinase tyrosine kinase. Variant anaplastic lymphoma kinase (ALK) translocations, all with a breakpoint at 2p23, have also been reported. T-cell LBL harbors many of the same cytogenetic abnormalities as T-cell acute lymphoblastic leukemia (T-ALL), including rearrangements with breakpoints at 14q11.2 involving the T-cell receptor, and t(5;14) translocation (20%), which does not involve the 14q11.2 breakpoint.

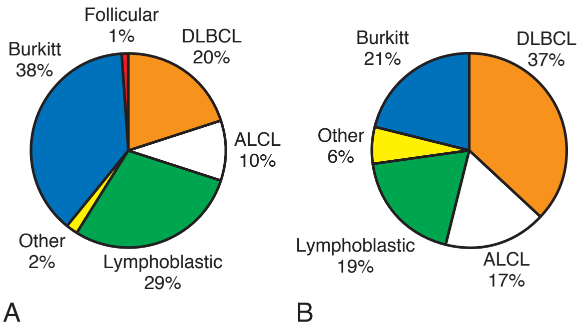

Figure 496-4 Incidence of non-Hodgkin lymphoma subtypes in **(A)** 0-14 yr age group and **(B)** 15-19 yr age group. *ALCL*, anaplastic large cell lymphoma; *DLBCL*, diffuse large B-cell lymphoma. *(Adapted from Hochberg J, Waxman IM, Kelly KM, et al: Adolescent non-Hodgkin lymphoma and Hodgkin lymphoma: state of the science*, Br J Haematol *144:24–40, 2008.)*

Genomic studies have offered insights into NHL pathogenesis as well as elucidated potential targets for novel therapies. Gene expression profiling of T-LBL and T-ALL has implicated the activation of oncogenic transcription factors as a result of aberrant T-cell receptor gene rearrangement. One of the most frequently activated signaling pathways is NOTCH1, which may be amenable to therapeutic targeting with γ-secretase inhibitors. In BL and DLBCL, extensive genomic work has identified unique gene expression signatures that differentiate these 2 mature B-cell neoplasms. In addition, next-generation sequencing of BL has identified genetic lesions in *TCF3* and *ID3*, which lead to activation of the AKT/PI3 kinase pathway. Other genetic lesions that have been described in BL include loss of function of the chromatin remodeling genes ARID1A and SMARCA4. Importantly, many of these alterations are potentially targetable by agents that are currently in development.

CLINICAL MANIFESTATIONS

The clinical manifestations of childhood and adolescent NHL depend primarily on pathologic subtype and sites of involvement. The staging system used for NHL is the St. Jude/Murphy classification (Table 496-5), although this classification schema is currently under an

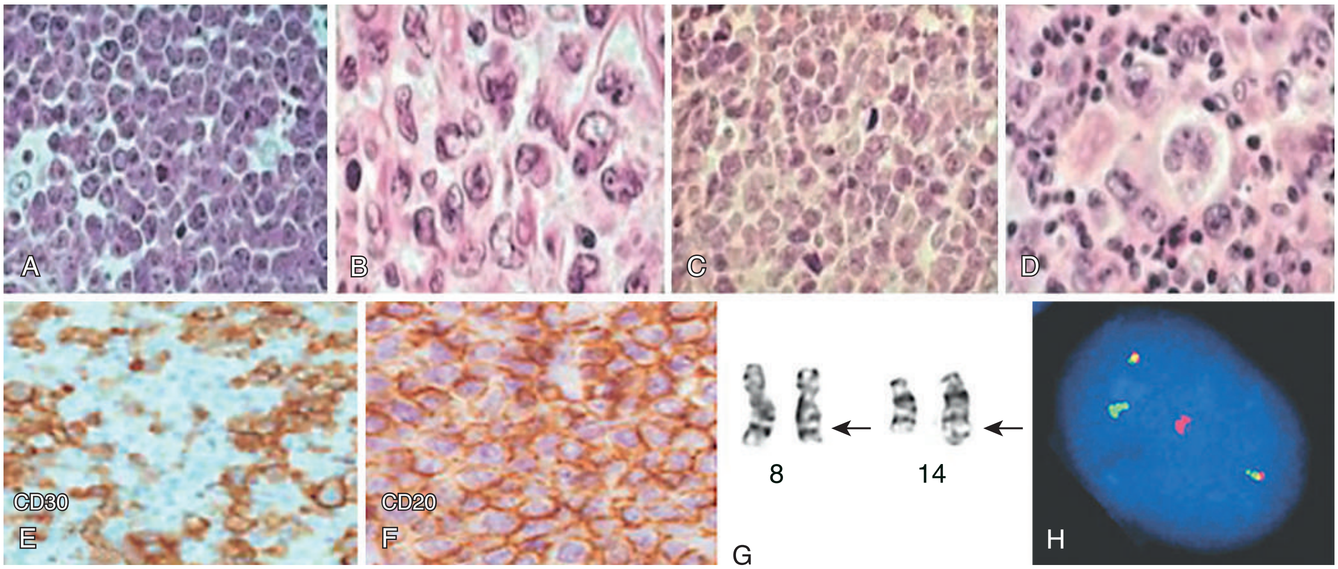

Figure 496-5 Histologic subtypes of childhood and adolescent non-Hodgkin lymphoma. **A-D:** Hematoxylin & eosin stains showing morphology of Burkitt lymphoma (**A,** high power), diffuse large B-cell lymphoma (**B,** high power), precursor T-lymphoblastic lymphoma (**C,** high power), and anaplastic large cell lymphoma (**D,** high power). **E-F:** Characteristic surface markers for ALCL (CD30; **E**) and BL (CD20; **F**). **G-H:** Cytogenetic analysis of BL demonstrating t(8;14). **G:** Karyotype showing the conventional t(8;14)(q24;q32). **H:** Interphase fluorescence in situ hybridization showing a balanced translocation involving MYC and immunoglobulin (Ig) H loci. The chromosome 8 centromere is labeled with spectrum aqua, MYC probe is labeled with spectrum orange, and IgH is labeled with spectrum green. Two fusion signals are seen as well as one red and one green representing the normal chromosomes. *(**A-D** from Cairo MS, Raetz E, Lim MS, et al: Childhood and adolescent non-Hodgkin lymphoma: new insights in biology and critical challenges for the future*, Pediatr Blood Cancer *45:753–769, 2005.* ***E-H*** *from Giulino-Roth, Cesarman E: Molecular biology of Burkitt lymphoma. Table 496-5 St. Jude Staging System for Childhood Non-Hodgkin Lymphoma

STAGE	DESCRIPTION
I	A single tumor (extranodal) or single anatomic area (nodal), with the exclusion of mediastinum or abdomen
II	A single tumor (extranodal) with regional node involvement Two or more nodal areas on the same side of the diaphragm Two single (extranodal) tumors with or without regional node involvement on the same side of the diaphragm A primary gastrointestinal tract tumor, usually in the ileocecal area, with or without involvement of associated mesenteric nodes only, which must be grossly (>90%) resected
III	Two single tumors (extranodal) on opposite sides of the diaphragm Two or more nodal areas above and below the diaphragm Any primary intrathoracic tumor (mediastinal, pleural, or thymic) Any extensive primary intraabdominal disease
IV	Any of the above, with initial involvement of central nervous system or bone marrow at time of diagnosis

From Murphy SB: Classification, staging and end results of treatment of childhood non-Hodgkin's lymphomas: dissimilarities from lymphomas in adults, Semin Oncol *7:332–339, 1980.*

Table 496-6 Risk Stratification Groups for Pediatric B-Cell NHL

Risk	Berlin-Frankfurt-Munster (BFM)	French-American-British (FAB)
Low Risk ↓	**R1** Stage I or II, completely resected	**Group A** Resected stage I and abdominal completely resected stage II
	R2 Stage I or II, not resected Stage III with LDH <500 U/L	**Group B** All patients not in Group A or C
	R3 Stage III with LDH ≥500 to <1000 U/L or Stage IV with LDH <1000 U/L and CNS-negative	
High Risk	**R4** Stage III or IV with LDH ≥1000 U/L and/or CNS-positive	**Group C** Bone marrow disease (≥25% L3 blasts) and/or CNS-positive

CNS, central nervous system; LDH, lactate dehydrogenase.

international revision. Patients are further classified based on risk categories according to pediatric international cooperative group trials (Table 496-6). Approximately 70% of patients with NHL present with advanced disease (stage III or IV), including extranodal disease with bone marrow and central nervous system (CNS) involvement. B symptoms of fever, weight loss, and night sweats can be seen, particularly in ALCL, but are not prognostic. Capillary leak syndrome may be seen in ALK+ ALCLs.

The primary site of tumor involvement and metastasis pattern varies by pathologic subtype. LBL commonly manifests as an intrathoracic or mediastinal supradiaphragmatic mass and also has a predilection for spreading to the bone marrow and CNS. BL commonly manifests as abdominal (sporadic type) or head and neck (endemic type) tumor and can metastasize to the bone marrow or CNS. DLBCL commonly manifests as either an abdominal or mediastinal primary and, rarely, disseminates to the bone marrow or CNS. ALCL manifests either as a primary cutaneous manifestation (10%) or as systemic disease (90%) with dissemination to liver, spleen, lung, or mediastinum. Bone marrow or CNS disease is rare in ALCL. Site-specific manifestations of NHL include painless, rapid lymph node enlargement; cough or dyspnea with thoracic involvement; superior mediastinal syndrome; ascites, increased abdominal girth or intestinal obstruction with an abdominal mass; nasal congestion, earache, hearing loss, or tonsil enlargement with Waldeyer ring involvement; and localized bone pain.

NHL can present as a life-threatening oncologic emergency. These manifestations are important to recognize as they require intensive supportive care and, in some cases, alterative treatment. Superior mediastinal syndrome can occur as a consequence of a large mediastinal mass causing obstruction of blood flow or respiratory airways. Spinal cord tumors can cause cord compression and acute paraplegias requiring emergent radiation therapy. Lastly, tumor lysis syndrome (TLS) can occur from rapid cell turnover, which is especially common in BL. TLS can result in severe metabolic abnormalities including hyperuricemia, hyperphosphatemia, hyperkalemia, and hypocalcemia. This can rapidly lead to renal insufficiency/failure as well as cardiac abnormalities if not aggressively treated.

LABORATORY FINDINGS

Recommended laboratory and radiologic testing includes complete blood cell count; measurements of electrolytes, lactate dehydrogenase, uric acid, calcium, phosphorus, blood urea nitrogen, creatinine, bilirubin, alanine aminotransferase, and aspartate aminotransferase; bone marrow aspiration and biopsy; lumbar puncture with cerebrospinal fluid cytology, cell count and protein; chest radiographs; and neck, chest, abdominal, and pelvic CT scans (head CT for suspicion of CNS disease), and PET scan. Tumor tissue (i.e., biopsy, bone marrow, cerebrospinal fluid, or pleurocentesis/paracentesis fluid) should be tested by flow cytometry for immunophenotypic origin (T, B, or null) and cytogenetics (karyotype). Additional tests might include fluorescent in situ hybridization or quantitative reverse transcription polymerase chain reaction for specific genetic translocations, T- and B-cell gene rearrangement studies, and molecular profiling by oligonucleotide microarray.

TREATMENT

The primary modality of treatment for childhood and adolescent NHL is **multiagent systemic chemotherapy with intrathecal chemotherapy** (see Table 496-4). Surgery is used mainly for diagnosis. Radiation therapy is used only in special circumstances, such as CNS involvement in LBL or, in the presence of acute superior mediastinal syndrome or paraplegias. Newly diagnosed patients, especially those with BL and LBL, are at high risk for TLS. These patients require vigorous hydration, frequent electrolyte monitoring, and either a xanthine oxidase inhibitor (allopurinol, 10 mg/kg/day PO divided into 3 doses daily) or recombinant urate oxidase (rasburicase, 0.2 mg/kg/day IV once daily for up to 5 days). Recombinant urate oxidase is preferred in patients with a high risk of tumor lysis. Frequently, only a single dose is needed; however, repeat doses can be given if a subsequent rise in uric acid is seen.

Burkitt Lymphoma and Diffuse Large B-cell Lymphoma

Pediatric BL and DLBCL are treated with similar chemotherapy regimens, which are designed for mature B-NHL. Regimens vary based on stage and risk stratification. For patients with localized disease, multiagent chemotherapy is given over a 6 wk to 6 mo period and the prognosis is excellent. In the international FAB/LMB 96 (French-American-British Lymphoma, mature B cell) trial, patients with

localized, completely resected disease received 2 cycles of COPAD (cyclophosphamide, vincristine, prednisone, and doxorubicin) resulting in a 4 yr OS of 99%. Advanced disease is usually treated with a 4-6 mo regimen of multiagent chemotherapy, such as FAB/LMB 96 protocol therapy or NHL-BFM (Berlin-Frankfurt-Munich) 95 protocol therapy with an OS of 79-90%. A subset of patients that likely require a different treatment approach are those with primary mediastinal B-cell lymphoma (PMBCL). PMBCL is a histologic subtype that represents 2% of mature B-NHLs. Pediatric patients with PMBCL have an inferior outcome when treated with standard mature B-NHL protocols (EFS of only 66%). Alternative treatment strategies, including rituximab and other novel agents, may be of benefit to this group.

Rituximab is a monoclonal antibody directed at CD20 that improves outcomes in adult patients with B-NHL. As nearly all pediatric BLs and DLBCLs express CD20, rituximab has been examined in pediatric B-NHL; however, the efficacy in this setting is not yet known. A window study of rituximab given to pediatric patients with newly diagnosed BL and DLBCL demonstrated its activity as a single agent with a response rate of 41%. Additionally, a Children's Oncology Group study examined the safety and pharmacokinetics of rituximab when added to standard chemotherapy for intermediate-risk patients. Rituximab was found to be safe, and survival in this cohort was the best reported to date (3 yr OS of 95%). In a similar cohort of CNS-positive patients, the addition of rituximab to the chemotherapy backbone resulted in a 93% EFS.

Lymphoblastic Lymphoma

Localized or advanced LBL requires 12-24 mo of therapy including chemotherapy, intrathecal therapy, and cranial radiation in some cases. The best results in advanced LBL have been obtained using the NHL-BFM 90 protocol, which uses therapeutic approaches similar to those for childhood acute leukemia, including induction, consolidation, interim maintenance, and reinduction (advanced disease only) phases as well as a year-long maintenance phase with 6-mercaptopurine and methotrexate. Studies have attempted to determine whether cranial radiation can be omitted, with promising results; however, the sample size in these studies is small. For patients with relapsed disease, the outcome is poor (OS of 10%) and novel treatments are needed. Nelarabine is a purine analog with significant T-lymphocyte toxicity; nelarabine has been investigated in T-LBL. Nelarabine is currently undergoing investigation in high-risk patients with T-ALL and T-LBL.

Anaplastic Large Cell Lymphoma

For patients who present with localized disease, surgical resection alone is sufficient. The majority of patients, however, have advanced disease, which requires multiagent chemotherapy. Various chemotherapy regimens have been studied with similar outcomes and survival ranging from 70-79%. CNS prophylaxis consists of intrathecal chemotherapy; however, it may be possible to omit this with the substitution of high-dose methotrexate. CNS disease, although rare, can be seen and is treated with intrathecal chemotherapy and cranial radiation.

Two novel targeted agents have shown substantial promise in early-phase trials in ALCL. The CD30 antibody–drug conjugate brentuximab and the ALK inhibitor crizotinib both have impressive activity and minimal toxicity in patients with relapsed ALCL. Given the high efficacy and low toxicity profile, it may be possible to use these agents in newly diagnosed patients to eliminate the reliance on and toxicity of conventional chemotherapy.

Relapsed Non-Hodgkin Lymphoma

Patients with NHL in whom progressive or relapsed disease develops require reinduction chemotherapy and either allogeneic or autologous stem cell transplantation (SCT). The specific reinduction regimen or transplantation type depends on the pathologic subtype, previous therapy, site of reoccurrence, and stem cell donor availability. Although there are no randomized trials examining autologous vs allogeneic SCT for relapsed NHL, data from retrospective studies suggest that outcomes are similar with the exception of LBL and ALCL where allogeneic SCT is superior, perhaps because of a graft-vs-lymphoma effect.

As relapsed NHL can be difficult to treat, efforts have been made to identify those patients at higher risk of relapse to tailor the initial therapy. The measurement of minimal residual disease may serve as a prognostic marker and aid in risk stratification. Minimal residual disease is prognostic in ALCL and LBL. In ALCL, there is also evidence that a humoral response to the ALK kinase can be used to predict outcome with a superior outcome in patients who mount an antibody titer to ALK. Minimal residual disease measurement in intermediate-risk B-NHL is feasible and is currently being evaluated in an international trial.

COMPLICATIONS

Patients receiving multiagent chemotherapy for advanced disease are at acute risk for serious mucositis, infections, cytopenias that require red blood cell and platelet blood product transfusions, electrolyte imbalances, and poor nutrition. Long-term complications include the risk of growth retardation, cardiac toxicity, gonadal toxicity with infertility, and secondary malignancies.

PROGNOSIS

The prognosis is excellent for most forms of childhood and adolescent NHL (see Table 496-4). Patients with localized disease have a 90-100% chance of survival, and those with advanced disease have a 70-95% chance of survival. As outcomes for pediatric patients with NHL have improved substantially, the focus has now shifted to minimizing the long-term toxicity of therapy. Novel targeted agents are desirable as they have the potential to improve outcomes and decrease the reliance on toxic conventional chemotherapy.

Bibliography is available at Expert Consult.

496.3 Late Effects in Children and Adolescents with Lymphoma

Jessica Hochberg, Lisa Giulino-Roth, and Mitchell S. Cairo

The majority of patients with newly diagnosed HL and NHL have OS rates above 90%. There are approximately 270,000 survivors of childhood cancer in the United States, which equates to about 1 of every 640 adults between the ages of 20 and 40 yr. However, this survival has often been achieved at the expense of an increased relative risk of long-term complications, including solid tumors, leukemia, cardiac disease, pulmonary complications, thyroid disease, and infertility. An analysis of more than 1,000 long-term childhood NHL survivors found increased rates of death >20 yr after treatment. A review of Surveillance, Epidemiology and End Results data over a 25 yr follow-up period demonstrates that the relative survival curves do not plateau after 10 yr following diagnosis of HL but, rather, accelerate. This finding highlights the importance of late morbidity and mortality among survivors of lymphoma. The first Childhood Cancer Survivor Study, a retrospective cohort study of 10,397 cancer survivors, shows that 62.3% of survivors report at least 1 chronic condition, with 27.5% reporting severe or life-threatening conditions. The survivor's adjusted relative risk of a severe or life-threatening chronic condition, compared with that of a sibling, was 8.2 (95% confidence interval, 6.9-9.7). When disease-specific health outcomes were looked at, both HL and NHL were found to be associated with a cumulative incidence of chronic health conditions approaching 70-80%, with severe conditions being reported in close to 50% of HL survivors (Fig. 496-6).

Chapter **497**

Brain Tumors in Childhood

Joann L. Ater and John F. Kuttesch Jr.

Primary central nervous system (CNS) tumors are a heterogeneous group of diseases that are, collectively, the second most common malignancy in childhood and adolescence. The overall mortality among this group approaches 30%. Patients with CNS tumors have the highest morbidity—primarily neurologic—of all children with malignancies. Outcomes have improved over time with innovations in neurosurgery and radiation therapy as well as the introduction of chemotherapy as a therapeutic modality. The treatment approach for these tumors is multimodal. Surgery with complete resection, if feasible, is the foundation, with radiation therapy and chemotherapy utilized according to the diagnosis, patient age, and other factors.

ETIOLOGY

The etiology of pediatric brain tumors is not well defined. A male predominance is noted in the incidence of medulloblastoma and ependymoma. Familial and hereditary syndromes associated with an increased incidence of brain tumors account for approximately 5% of cases (Table 497-1). Cranial exposure to ionizing radiation also is associated with a higher incidence of brain tumors. There are sporadic reports of brain tumors within families without evidence of a heritable syndrome. The molecular events associated with tumorigenesis of pediatric brain tumors are not known.

EPIDEMIOLOGY

Approximately 4,600 primary brain tumors are diagnosed each year in children and adolescents in the United States, with an overall annual incidence of approximately 47 cases/1 million children younger than 20 yr of age. The incidence of CNS tumors is highest in infants and children 5 yr of age or younger (approximately 52 cases/1 million children).

PATHOGENESIS

More than 100 histologic categories and subtypes of primary brain tumors are described in the World Health Organization (WHO) classification of tumors of the CNS. In children 0-14 yr of age, the most common tumors are pilocytic astrocytomas (PAs) and medulloblastoma/primitive neuroectodermal tumors (PNETs). In adolescents (15-19 yr), the most common tumors are pituitary tumors and PAs (Fig. 497-1).

The Surveillance, Epidemiology, and End Results program reported a slight predominance of infratentorial tumor location (43.2%), followed by the supratentorial region (40.9%), spinal cord (4.9%), and multiple sites (11%) (Fig. 497-2, Table 497-2). There are age-related differences in primary location of tumor. During the 1st yr of life, supratentorial tumors predominate and include, most commonly, choroid plexus complex tumors and teratomas. In children 1-10 yr of age, infratentorial tumors predominate, owing to the high incidence of juvenile PA and medulloblastoma. After 10 yr of age, supratentorial tumors again predominate, with diffuse astrocytomas most common. Tumors of the optic pathway and hypothalamus region, the brainstem, and the pineal–midbrain region are more common in children and adolescents than in adults.

CLINICAL MANIFESTATIONS

The clinical presentation of the patient with a brain tumor depends on the tumor location, the tumor type, and the age of the child. Signs and symptoms are related to obstruction of cerebrospinal fluid (CSF) drainage paths by the tumor, leading to **increased intracranial pressure (ICP)** or causing focal brain dysfunction. Subtle changes in personality, mentation, and speech may precede these classic signs and symptoms; such changes often occur with supratentorial (cortical) lesions. In young children, the diagnosis of a brain tumor may be delayed because the symptoms are similar to those of more common illnesses, such as gastrointestinal disorders, with associated vomiting. Infants with open cranial sutures may present with signs of increased ICP, such as vomiting, lethargy, and irritability, as well as the later finding of macrocephaly. The **classic triad** of headache, nausea, and vomiting as well as papilledema is associated with midline or infratentorial tumors. Disorders of equilibrium, gait, and coordination occur with infratentorial tumors. **Torticollis** may occur in cases of cerebellar tonsil herniation. Blurred vision, diplopia, and nystagmus also are associated with infratentorial tumors. Tumors of the brainstem region may be associated with gaze palsy, multiple cranial nerve palsies, and upper motor neuron deficits (e.g., hemiparesis, hyperreflexia, clonus). **Supratentorial tumors** are more commonly associated with lateralized deficits, such as focal motor weakness, focal sensory changes, language disorders, focal seizures, and reflex asymmetry. Infants with supratentorial tumors may present with premature hand preference. Optic pathway tumors manifest as visual and/or afferent oculomotor disturbances, such as decreased visual acuity, Marcus Gunn pupil (afferent pupillary defect), nystagmus, and/or visual field defects. Suprasellar region tumors and third ventricular region tumors may manifest initially as **neuroendocrine deficits,** such as subacute development of obesity, abnormal linear growth velocity, diabetes insipidus, galactorrhea, precocious puberty, delayed puberty, and hypothyroidism. In fact, signs of endocrine dysfunction preceded symptoms of neuroophthalmologic dysfunction by an average of 1.9 yr, and their recognition as a possible sign of hypothalamic or pituitary neoplasm can hasten diagnosis and improve outcome. The **diencephalic syndrome,** which manifests as failure to thrive, emaciation despite normal caloric intake, and inappropriately normal or happy affect, occurs in infants and young children with tumors in these regions. **Parinaud syndrome** is seen with pineal region tumors and is manifested by paresis of upward gaze, pupillary caliber reactive to accommodation but not to light (pseudo-Argyll Robertson pupil), nystagmus to convergence or retraction, and eyelid retraction. Spinal cord tumors and spinal cord dissemination of brain tumors may manifest as long nerve tract motor and/or sensory

Table 497-1 Familial Syndromes Associated with Pediatric Brain Tumors

SYNDROME	CENTRAL NERVOUS SYSTEM MANIFESTATIONS	CHROMOSOME	GENE
Neurofibromatosis type 1 (autosomal dominant)	Optic pathway gliomas, astrocytoma, malignant peripheral nerve sheath tumors, neurofibromas	17q11	*NF1*
Neurofibromatosis type 2 (autosomal dominant)	Vestibular schwannomas, meningiomas, spinal cord ependymoma, spinal cord astrocytoma, hamartomas	22q12	*NF2*
von Hippel–Lindau (autosomal dominant)	Hemangioblastoma	3p25-26	*VHL*
Tuberous sclerosis (autosomal dominant)	Subependymal giant cell astrocytoma, cortical tubers	9q34 16q13	*TSC1* *TSC2*
Li-Fraumeni (autosomal dominant)	Astrocytoma, primitive neuroectodermal tumor	17q13	*TP53*
Cowden (autosomal dominant)	Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease)	10q23	*PTEN*
Turcot (autosomal dominant)	Medulloblastoma Glioblastoma	5q21 3p21 7p22	*APC* *hMLH1* *hPSM2*
Nevoid basal cell carcinoma Gorlin (autosomal dominant)	Medulloblastoma	9q31	*PTCH1*

Modified from Kleihues P, Cavenee WK: World Health Organization classification of tumors: pathology and genetics of tumors of the nervous system, *Lyon, 2000, IARC Press.*

deficits often localized to below a specific spinal level, bowel and bladder deficits, and back or radicular pain. The signs and symptoms of meningeal metastatic disease from brain tumors or leukemia include head or back pain and symptoms referable to compression of cranial nerves or spinal nerve roots.

DIAGNOSIS

The evaluation of a patient in whom a brain tumor is suspected is an emergency. Initial evaluation should include a complete history, physical (including ophthalmic) examination, and neurologic assessment with neuroimaging. For primary brain tumors, **MRI** with and without gadolinium is the neuroimaging standard. Tumors in the pituitary/suprasellar region, optic path, and infratentorium are better delineated with MRI than with CT. Patients with tumors of the midline and the pituitary/suprasellar/optic chiasmal region should undergo evaluation for **neuroendocrine dysfunction.** Formal ophthalmologic examination is beneficial in patients with optic path region tumors to document the impact of the disease on oculomotor function, visual acuity, and fields of vision. The suprasellar and pineal regions are preferential sites for germ cell tumors (Fig. 497-3). Both serum and CSF measurements of **β-human chorionic gonadotropin** and **α-fetoprotein** can assist in the diagnosis of germ cell tumors. In tumors with a propensity for spreading to the leptomeninges, such as medulloblastoma/PNET, ependymoma, and germ cell tumors, lumbar puncture with cytologic analysis of the CSF is indicated; lumbar puncture is contraindicated in individuals with newly diagnosed hydrocephalus secondary to CSF flow obstruction, in tumors that cause supratentorial midline shift, and in individuals with infratentorial tumors. Lumbar puncture in

these individuals may lead to brain herniation, resulting in neurologic compromise and death. Therefore, in children with newly diagnosed intracranial tumors and signs of increased ICP, the lumbar puncture usually is delayed until surgery or shunt placement.

SPECIFIC TUMORS

Astrocytomas

Astrocytomas are a heterogeneous group of tumors that account for approximately 40% of pediatric CNS malignancies. These tumors occur throughout the CNS.

Low-grade astrocytomas (LGAs), the predominant group of astrocytomas in childhood, are characterized by an indolent clinical course. **PA** is the most common astrocytoma in children, accounting for approximately 20% of all brain tumors. On the basis of clinicopathologic features using the WHO Classification System, PA is classified as a WHO grade I tumor. Although PA can occur anywhere in the CNS, the classic site is the **cerebellum** (Fig. 497-4*A*). Other common sites include the hypothalamic/third ventricular region and the optic nerve and chiasmal region (Fig. 497-4*B*). The classic but not exclusive neuroradiologic finding in PA is the presence of a contrast medium–enhancing nodule within the wall of a cystic mass (Fig. 497-4*A*). The microscopic findings include the biphasic appearance of bundles of compact fibrillary tissue interspersed with loose microcystic, spongy areas. The presence of **Rosenthal fibers,** which are condensed masses of glial filaments occurring in the compact areas, helps establish the diagnosis. PA has a low metastatic potential and is rarely invasive. A

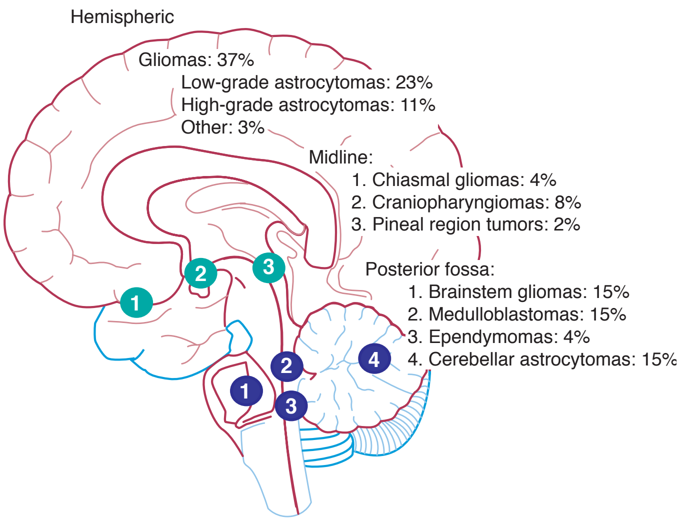

Figure 497-2 **Childhood brain tumors occur at any location within the central nervous system.** The relative frequency of brain tumor histologic types and the anatomic distribution are shown. *(Redrawn from Albright AL: Pediatric brain tumors,* CA Cancer J Clin *43:272–288, 1993.)*

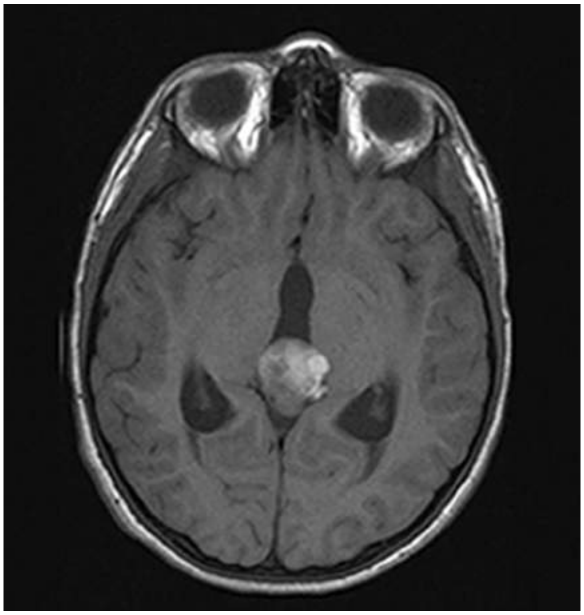

Figure 497-3 Axillary T1-weighted MR image with gadolinium of a 10 yr old boy presenting with mixed germ cell tumor of the pineal region, with early onset of puberty, headaches, and elevated α-fetoprotein and β–human chorionic gonadotropin in the spinal fluid and serum.

Table 497-2 Posterior Fossa Tumors of Childhood

TUMOR	RELATIVE INCIDENCE (%)	PRESENTATION	DIAGNOSIS	PROGNOSIS
Medulloblastoma	35-40	2-3 mo of headaches, vomiting, truncal ataxia	Heterogeneously or homogeneously enhancing fourth ventricular mass; may be disseminated	65-85% survival; dependent on stage/type; poorer (20-70%) in infants
Cerebellar astrocytoma	35-40	3-6 mo of limb ataxia; secondary headaches, vomiting	Cerebellar hemisphere mass, usually with cystic and solid (mural nodule) components	90-100% survival in totally resected pilocytic type
Brainstem glioma	10-15	1-4 mo of double vision, unsteadiness, weakness, and cranial nerve dysfunction, including facial weakness, swallowing dysfunction, and oculomotor abnormalities	Diffusely expanded, minimally or partially enhancing mass in 80%; 20% more focal tectal or cervicomedullary lesion	>90% mortality in diffuse tumors; better in localized
Ependymoma	10-15	2-5 mo of unsteadiness, headaches, double vision, and facial asymmetry	Usually enhancing, fourth ventricular mass with cerebellopontine predilection	>75% survival in totally resected lesions
Atypical teratoid/rhabdoid	>5 (10-15% of infantile malignant tumors)	As in medulloblastoma, but primarily in infants; often associated facial weakness and strabismus	As in medulloblastoma, but often more laterally extended	≤20% survival in infants

Modified from Packer RJ, MacDonald T, Vezina G: Central nervous system tumors, Pediatr Clin North Am *55:121–145, 2008.*

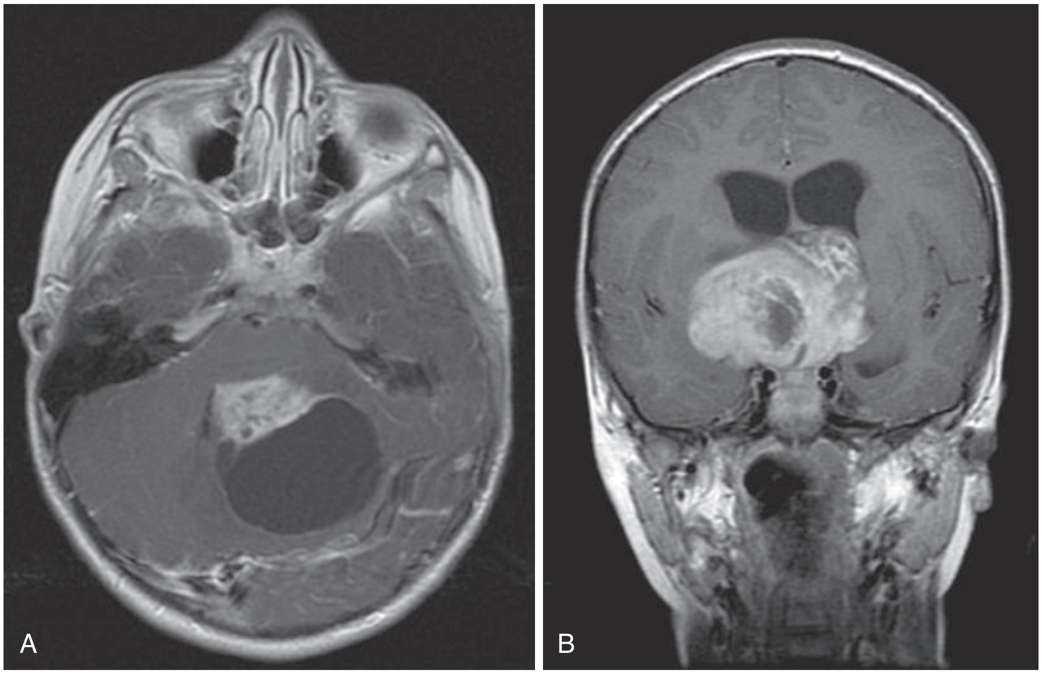

Figure 497-4 **A,** Gadolinium-enhanced axial T1-weighted MR image in a 4 yr old child with cerebellar pilocytic astrocytoma presenting with headaches, emesis, and ataxia demonstrates a predominantly cystic mass with enhancement of the solid component and enhancement of the capsule. **B,** Gadolinium-enhanced coronal view of a cystic juvenile pilocytic astrocytoma of the suprasellar region from a 4 yr old child presenting with visual loss and headaches.

small proportion of these tumors can progress and develop leptomeningeal spread, particularly when they occur in the optic path region. A PA very rarely undergoes malignant transformation to a more aggressive tumor. A PA of the optic nerve and chiasmal region is a relatively common finding in patients with neurofibromatosis type 1 (15% incidence). Unlike in diffuse fibrillary astrocytomas, there are no characteristic cytogenetic abnormalities in PA. Other tumors occurring in the pediatric age group with clinicopathologic characteristics similar to those of PA include pleomorphic xanthoastrocytoma, desmoplastic cerebral astrocytoma of infancy, and subependymal giant cell astrocytoma.

The second most common astrocytoma is **fibrillary infiltrating astrocytoma,** which consists of a group of tumors characterized by a pattern of diffuse infiltration of tumor cells amidst normal neural tissue and potential for anaplastic progression. On the basis of their clinicopathologic characteristics, they are grouped as LGAs (WHO grade II), malignant astrocytomas (anaplastic astrocytoma; WHO grade III), and glioblastoma multiforme (WHO grade IV). Fibrillary LGA accounts for 15% of brain tumors. Histologically, these low-grade tumors demonstrate greater cellularity than normal brain parenchyma, with few mitotic figures, nuclear pleomorphism, and microcysts. The characteristic MRI finding is a lack of enhancement after contrast agent infusion. Molecular genetic abnormalities found among low-grade diffuse infiltrating astrocytomas include mutations of *P53* and overexpression of platelet-derived growth factor α-chain and platelet-derived growth factor receptor-α. **Evolution of fibrillary infiltrating astrocytoma** into malignant astrocytoma is associated with cumulative acquisition of multiple molecular abnormalities.

Pilomyxoid astrocytoma occurs most commonly in the hypothalamic/optic chiasmic region and carries a high risk of local as well as cerebrospinal spread. This astrocytoma affects young children and infants. It is classified as a WHO grade II tumor.

The **clinical management** of LGAs focuses on a multimodal approach incorporating surgery as the primary treatment as well as radiation therapy and chemotherapy. With complete surgical resection the overall survival approaches 80-100%. In patients with partial resection (<80% resection), overall survival varies from 50-95%, depending on the anatomic location of the tumor. In the patient who has undergone partial tumor resection and has stable neurologic status, the current approach is to follow the patient closely by examination and imaging. With evidence of progression, a second surgical resection should be considered. In patients in whom a second procedure was less than complete or is not feasible, radiation therapy is beneficial. Radiation therapy is delivered to the tumor bed at a total cumulative dose ranging from 50-55 Gy given on a daily schedule over 6 wk. Historically, patients with deep midline tumors have been treated empirically with radiation therapy and without surgery or biopsy, with variable survival rates from 33-75%. Modern surgical techniques and innovative radiation therapy methodology, including proton-beam radiation, may have a positive impact on the survival and clinical outcome of these patients. The role of chemotherapy in the management of LGAs is evolving. Because of concerns regarding morbidity from radiation therapy in young children, several chemotherapy approaches have been evaluated, especially in children younger than 10 yr of age. Complete response to chemotherapy is uncommon; however, these approaches have yielded durable control of disease in 70-100% of patients. Patients with midline tumors in the hypothalamic/optic chiasmatic region (see Fig. 497-4*B*) have tended to do less well. Taken together, the chemotherapy approaches have permitted delay and, potentially, avoidance of radiation therapy. Chemotherapy agents given singly or in combination for LGA include carboplatin, vincristine, lomustine, procarbazine, temozolomide, and vinblastine. Observation is the primary approach in clinical management of selected patients with LGAs that are biologically indolent. One such group includes patients with neurofibromatosis type 1, in whom an LGA of the optic chiasm/optic pathway or brainstem may be found incidentally. Another group includes patients with midbrain astrocytoma who have resolution of clinical symptoms after ventricular shunting and do not require further intervention. Astrocytomas associated with tuberous sclerosis have responded to everolimus, a mammalian target of rapamycin inhibitor.

Malignant astrocytomas are much less common in children and adolescents than in adults, accounting for 7-10% of all childhood tumors. Among this group, **anaplastic astrocytoma** (WHO grade III,

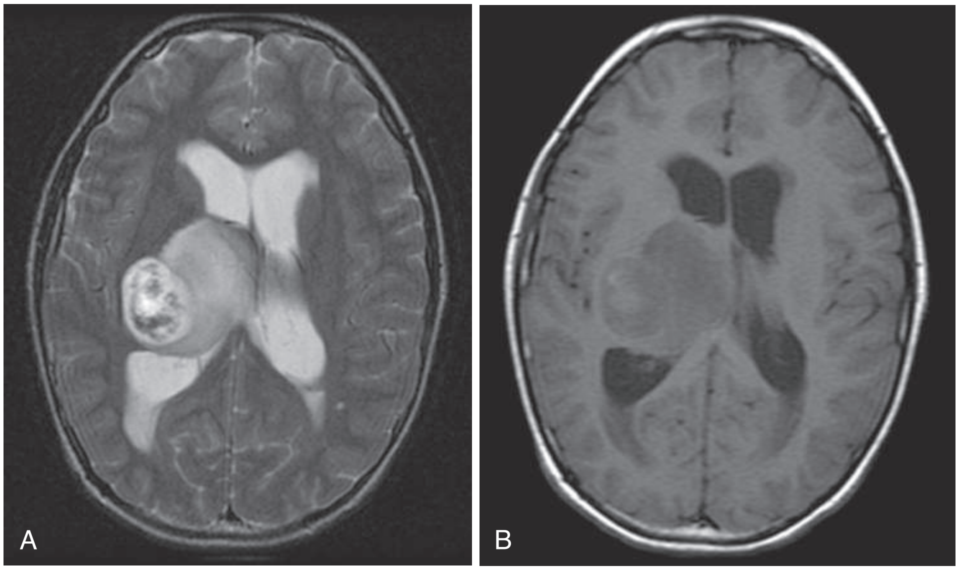

Figure 497-5 **A,** Nonenhanced axial T2-weighted MR image of grade III astrocytoma of the right thalamus demonstrating diffuse hyperintensity and area of necrotic cyst formation. **B,** Gadolinium-enhanced sagittal T1-weighted MR image showing slight enhancement and hypodensity of grade III astrocytoma of the thalamus. This 14 yr old child presented with left arm and leg numbness and weakness and right-sided headaches.

Fig. 497-5) is more common than **glioblastoma multiforme** (WHO grade IV). The histopathology of anaplastic astrocytomas demonstrates greater cellularity than that of low-grade diffuse astrocytomas, with cellular and nuclear atypia, presence of mitoses, and, variably, microvascular proliferation. Characteristic histopathologic findings in glioblastoma multiforme include dense cellularity, high mitotic index, microvascular proliferation, and foci of tumor necrosis. Limited information is available regarding the molecular abnormalities in malignant astrocytomas in children. Overexpression of *P53* in malignant astrocytoma in a child is an adverse prognostic factor. The frequency of mutations in *P53* and of the loss of heterozygosity at 19q and 22q in childhood malignant astrocytomas are similar to that noted in adults, although the frequency of such mutations in malignant astrocytomas of children younger than 3 yr of age is lower. This finding suggests differing mechanisms of oncogenesis in younger and older children, respectively. Optimal therapeutic approaches for malignant astrocytomas have yet to be defined. Standard therapy continues to be surgical resection followed by involved-field radiation therapy. A study of adult glioblastoma showed significantly better survival with temozolomide during and after irradiation than with irradiation alone. Current therapeutic approaches incorporate novel chemotherapeutic agents with radiation therapy. Enrollment in a clinical trial may be the best therapeutic option in these tumors where standard therapy is suboptimal.

Oligodendrogliomas are uncommon tumors of childhood. These infiltrating tumors occur predominantly in the cerebral cortex and originate in the white matter. Histologically, oligodendrogliomas consist of rounded cells with little cytoplasm and microcalcifications. Observation of a **calcified cortical mass** on CT in a patient presenting with a seizure is suggestive of oligodendroglioma. Treatment approaches are similar to those for infiltrating astrocytomas.

Ependymal Tumors

Ependymal tumors are derived from the ependymal lining of the ventricular system. Ependymoma (WHO grade II) is the most common of these neoplasms, occurring predominantly in childhood and accounting for 10% of childhood tumors. Approximately 70% of ependymomas in childhood occur in the posterior fossa. The mean age of patients is 6 yr, with approximately 40% of cases occurring in children younger than 4 yr of age. The incidence of leptomeningeal spread approaches 10% overall. Clinical presentation can be insidious and often depends on the anatomic location of the tumor. MRI demonstrates a well-circumscribed tumor with variable and complex patterns of gadolinium enhancement, with or without cystic structures (Fig. 497-6). These tumors usually are noninvasive, extending into the ventricular lumen and/or displacing normal structures, sometimes leading to significant obstructive hydrocephalus. Histologic characteristics include perivascular pseudorosettes, ependymal rosettes, monomorphic nuclear morphology, and occasional nonpalisading foci of necrosis. Other histologic subtypes include anaplastic ependymoma (WHO grade III), which is much less common in childhood and is characterized by a high mitotic index and histologic features of microvascular proliferation and pseudopalisading necrosis. Myxopapillary ependymoma (WHO grade I) is a slow-growing tumor arising from the filum terminale and conus medullaris and appears to be a biologically different subtype. There are no well-defined characteristic cytogenetic or molecular genetic alterations in ependymoma, largely owing to their heterogeneous nature, although association of various genotypes with susceptibility to ependymoma have been implicated. Preliminary studies suggest that there are genetically distinct subtypes of ependymoma, exemplified by an association between alterations in the *NF2* gene and spinal ependymoma. Surgery is the primary treatment modality, with extent of surgical resection a major prognostic factor. Two other major prognostic factors are age, with younger children having poorer outcomes, and tumor location, with localization in the posterior fossa, which often is seen in young children, associated with poorer outcomes. Surgery alone is rarely curative. Multimodal therapy incorporating irradiation with surgery has resulted in long-term survival in approximately 40% of patients with ependymoma undergoing gross total resection. Recurrence is predominantly local. Ependymoma is sensitive to a spectrum of chemotherapeutic agents; the role of chemotherapy in multimodal therapy of ependymoma is still unclear. Current investigations are directed toward identification of optimal radiation dose, surgical questions addressing the use of second-look procedures after chemotherapy, and further evaluation of classic as well as novel chemotherapeutic agents.

Choroid Plexus Tumors

Choroid plexus tumors account for 2-4% of childhood CNS tumors. They are the most common CNS tumor in children younger than 1 yr of age and account for 10-20% of CNS tumors in infants. These tumors are intraventricular epithelial neoplasms arising from the choroid plexus. Children present with signs and symptoms of increased ICP.

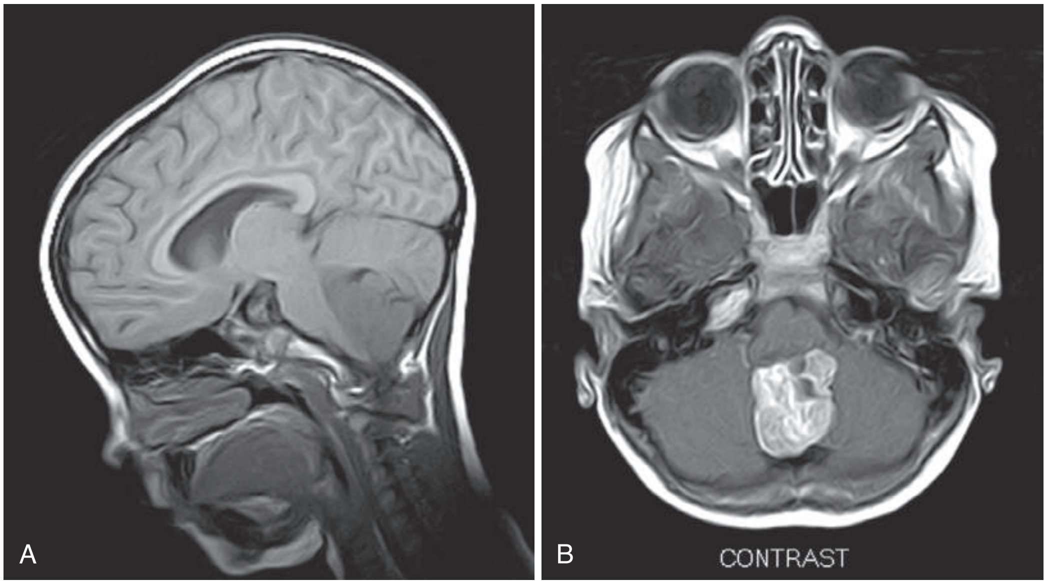

Figure 497-6 **A,** Sagittal T1-weighted MR image of a 6 yr old patient with ependymoma, demonstrating a hypointense mass within the fourth ventricle compressing the brainstem. **B,** Gadolinium-enhanced axial T1-weighted image of an ependymoma showing an enhancing mass within the fourth ventricle.

Infants may present with macrocephaly and focal neurologic deficits. In children, these tumors predominantly occur supratentorially in the lateral ventricles. **Choroid plexus papilloma** (WHO grade I), the most common of this group, is a well-circumscribed lesion on neuroimaging and closely resembles normal choroid plexus histologically. **Choroid plexus carcinoma** (WHO grade III) is a malignant tumor with metastatic potential to seed into the CSF pathways. This malignancy has the following histologic characteristics: nuclear pleomorphism, high mitotic index, and increased cell density. Immunopositivity for transthyretin (prealbumin) is useful in confirming the diagnosis of choroid plexus tumors. These tumors are associated with the **Li-Fraumeni syndrome. Simian virus 40** may also play an etiologic role in choroid plexus tumors. After complete surgical resection, the frequency of cure for choroid plexus papilloma approaches 100%, whereas the frequency of cure for choroid plexus carcinoma approaches 20-40%. Reports suggest that radiation therapy and/or chemotherapy may lead to better disease control for choroid plexus carcinoma.

Embryonal Tumors

Embryonal tumors or **PNETs** are the most common group of *malignant* CNS tumors of childhood, accounting for approximately 20% of pediatric CNS tumors. They have the potential to metastasize to the neuraxis and beyond. The group includes medulloblastoma, supratentorial PNET, ependymoblastoma, medulloepithelioblastoma, and atypical teratoid/rhabdoid tumor, all of which are histologically classified as WHO grade IV tumors.

Medulloblastoma, which accounts for 90% of embryonal CNS tumors, is a cerebellar tumor occurring predominantly in males and at a median age of 5-7 yr. Most of these tumors occur in the midline cerebellar vermis; however, older patients may present with tumors in the cerebellar hemisphere. CT and MRI demonstrate a solid, homogeneous, contrast medium–enhancing mass in the posterior fossa causing fourth ventricular obstruction and hydrocephalus (Fig. 497-7). Up to 30% of patients with medulloblastoma present with neuroimaging evidence of leptomeningeal spread. Among a variety of diverse histologic patterns of this tumor, the most common is a monomorphic sheet of undifferentiated cells classically noted as small, blue, round cells. Neuronal differentiation is more common among these tumors and is characterized histologically by the presence of Homer Wright rosettes and by immunopositivity for synaptophysin. An anaplastic variant is often more aggressive and may be associated with worse prognosis. Patients present with signs and symptoms of increased ICP (i.e., headache, nausea, vomiting, mental status changes, and hypertension) and cerebellar dysfunction (i.e., ataxia, poor balance, dysmetria). Standard clinical staging evaluation includes MRI of the brain and spine, both preoperatively and postoperatively, as well as lumbar puncture after the increased ICP has resolved. The Chang staging system, originally based on surgical information, has been modified to incorporate information from neuroimaging to identify risk categories. Clinical features that have consistently demonstrated prognostic significance include age at diagnosis, extent of disease, and extent of surgical resection. Patients younger than 4 yr of age have a poor outcome, partly as the result of a higher incidence of disseminated disease on presentation and past therapeutic approaches that have used less intense therapies. Patients with disseminated disease at diagnosis (M >0), including positive CSF cytologic result alone (M1), have a markedly worse outcome than those patients with no dissemination (M0). Similarly, patients with gross residual disease after surgery have worse outcomes than those in whom surgery achieved gross total resection of disease.

Cytogenetic and molecular genetic studies have demonstrated multiple abnormalities in medulloblastoma. The most common abnormality involves chromosome 17p deletions, which occur in 30-40% of all cases. These deletions are not associated with *P53* mutations. Several signaling pathways have been shown to be active in medulloblastomas, including the sonic hedgehog (SHH) pathway, predominately associated with the desmoplastic variants, and the WNT pathway, which can occur in up to 15% of cases and has been associated with improved survival. Integrative genomic studies have recently identified at least 4 distinct molecular subgroups of medulloblastoma—WNT, SHH, group 3, and group 4—which exhibit highly discriminate transcriptional, cytogenetic, and mutational spectra, in addition to divergent patient demographics and clinical behavior. These prognostic groups still must be validated in larger prospective studies. With the evolution of gene array technology, preliminary studies have identified clusters of genes/gene expression that appear to be associated with metastatic medulloblastoma and outcome.

A multimodal treatment approach is pursued in medulloblastoma, with surgery as the starting point of treatment. Medulloblastoma is sensitive to both chemotherapy and radiation therapy. With technologic advances in neurosurgery, neuroradiology, and radiation therapy, as well as identification of chemotherapy as an effective modality, the overall outcome among all patients approaches 60-70%. Standard

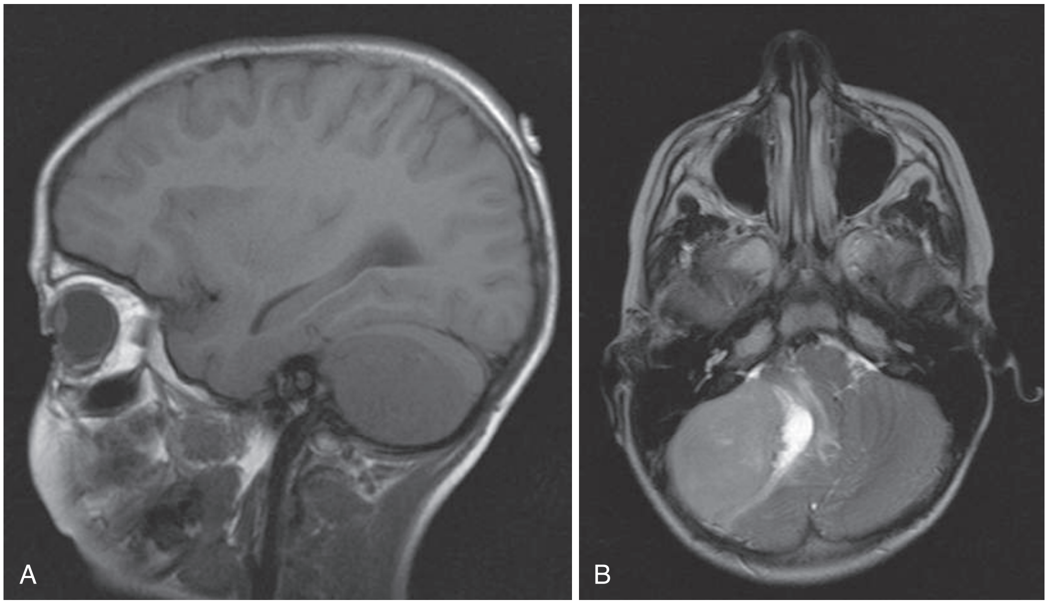

Figure 497-7 **A,** Sagittal T1-weighted MR image shows hypointense mass involving the cerebellar hemisphere in a 6 yr old child with desmoplastic variant of medulloblastoma. **B,** Axial T2-weighted image of the same child shows hyperintense mass involving the cerebellar hemisphere.

radiation treatment in standard risk medulloblastoma incorporates craniospinal radiation at a total cumulative dose of 24 Gy, with a cumulative dose of 50-55 Gy to the tumor bed. Craniospinal radiation at this dose in children younger than 3 yr of age results in severe late neurologic sequelae, including microcephaly, learning disabilities, cognitive impairment, neuroendocrine dysfunction (growth failure, hypothyroidism, hypogonadism, and absence/delay of puberty), and/or second malignancies. Similarly, in older children, late sequelae, such as learning disabilities, neuroendocrine dysfunction, and/or second malignancies, can occur. These observations have resulted in stratification of treatment approaches into the following 3 strata: (1) patients younger than 3 yr of age; (2) standard-risk patients older than 3 yr of age with surgical total resection and no disease dissemination (M0); and (3) high-risk patients older than 3 yr of age with disease dissemination (M >0) and/or bulky residual disease after surgery. With the risk-based approach to treatment, children with high-risk medulloblastoma receive high-dose cranial–spinal radiation (36 Gy) with chemotherapy during and after radiation therapy, and those with standard-risk (nonmetastatic) disease receive lower-dose craniospinal radiation (24 Gy) with chemotherapy during and after radiation therapy. Because the dose of radiation depends on the risk stratification, complete staging with MRI of the spine before starting treatment is essential for the best chance of survival. Approaches in young children (younger than 4 yr of age) incorporate high-dose chemotherapy with peripheral stem cell reinfusion and exclude radiation therapy. Overall survival in children with nonmetastatic medulloblastoma and gross total tumor resection approaches 85%. The presence of bulky residual tumor (56% survival) or metastases (38% survival) confers a poor prognosis.

Supratentorial primitive neuroectodermal tumors (SPNETs) account for 2-3% of childhood brain tumors, primarily in children within the 1st decade of life. These tumors are similar histologically to medulloblastoma and are composed of undifferentiated or poorly differentiated neuroepithelial cells. Historically, patients with SPNETs have had poorer outcomes than those with medulloblastoma after combined-modality therapy. In current clinical trials, children with SPNETs are considered among the high-risk group and receive dose-intense chemotherapy with craniospinal radiation therapy.

Atypical teratoid/rhabdoid tumor is a very aggressive embryonal malignancy that occurs predominantly in children younger than 5 yr of age and can occur at any location in the neuraxis. The histology demonstrates a heterogeneous pattern of cells, including rhabdoid cells that express epithelial membrane antigen and neurofilament antigen. The characteristic cytogenetic pattern is partial or complete deletion of chromosome 22q11.2 that is associated with mutation in the *INI1* gene. The relation between this mutation and tumorigenesis is unclear. Outcome after combined-modality therapy with intensive chemotherapy is very poor and there is no standard chemotherapy. However, long-term survival is reported for some children, primarily with complete resection and focal radiotherapy.

Pineal Parenchymal Tumors

The pineal parenchymal tumors are the most common malignancies after germ cell tumors that occur in the pineal region. These include pineoblastoma, occurring predominantly in childhood, pineocytoma, and the mixed pineal parenchymal tumors. The therapeutic approach in this group of diseases is multimodal. There was significant concern regarding the location of these masses and the potential complications of surgical intervention. With developments in neurosurgical technique and surgical technology, the morbidity and mortality associated with these approaches have markedly decreased. Stereotactic biopsy of these tumors may be adequate to establish diagnosis; however, consideration should be given to total resection of the lesion before institution of additional therapy. Pineoblastoma, the more malignant variant, is considered a subgroup of childhood PNETs. Chemotherapy regimens incorporate cisplatin, cyclophosphamide (Cytoxan), etoposide (VP-16), and vincristine and/or lomustine. Data have shown that survival outcome of combined chemotherapy and radiation therapy in pineal-region PNETs approaches 70% at 5 yr, similar to that noted for medulloblastoma. Pineocytoma usually is approached with surgical resection.

Craniopharyngioma

Craniopharyngioma (WHO grade I) is a common tumor of childhood, accounting for 7-10% of all childhood tumors. The adamantinomatous variant of craniopharyngioma predominates in childhood. Children with craniopharyngioma often present with endocrinologic abnormalities such as growth failure and delayed sexual maturation. Visual changes can occur and may include decreased acuity or visual field abnormalities. These tumors are often quite large and heterogeneous, displaying both solid and cystic components, and occur within the suprasellar region. They are minimally invasive, adhere to

adjacent brain parenchyma, and engulf normal brain structures. MRI demonstrates the solid tumor with cystic structures containing fluid of intermediate density. CT may show calcifications associated with the solid and cystic wall components. Surgery is the primary treatment modality, with gross total resection curative in small lesions. Controversy exists regarding the relative roles of surgery and radiation therapy in large, complex tumors. Significant morbidity (panhypopituitarism, growth failure, visual loss) is associated with these tumors and their therapy, owing to the anatomic location. There is no role for chemotherapy in craniopharyngioma.

Germ Cell Tumors

Germ cell tumors of the CNS are a heterogeneous group of tumors that are primarily tumors of childhood, arising predominantly in midline structures of the pineal and suprasellar regions (see Fig. 497-3). They account for 3-5% of pediatric brain tumors. The peak incidence of these tumors is in children 10-12 yr of age. Overall, there is a male preponderance, although there is a female preponderance for suprasellar tumors. Germ cell tumors occur multifocally in 5-10% of cases. This group of tumors is much more prevalent in Asian populations than European populations. Delays in diagnosis can occur because these tumors have a particularly insidious course; the initial presenting symptoms may be subtle, including poor school performance and behavior problems. As in peripheral germ cell tumors, the analysis of protein markers, **α-fetoprotein,** and **β-human chorionic gonadotropin** may be useful in establishing the diagnosis and monitoring treatment response. Surgical biopsy is recommended to establish the diagnosis; however, nongerminomatous germ cell tumors may be diagnosed on the basis of protein marker elevations. Therapeutic approaches to germinomas and mixed germ cell tumors are different. The survival proportion among patients with pure germinoma exceeds 90%. The postsurgical treatment of pure germinomas is somewhat controversial in defining the relative roles of chemotherapy and radiation therapy. Clinical trials have investigated the use of chemotherapy and reduced-dose radiation after surgery in pure germinomas. The therapeutic approach to nongerminomatous germ cell tumors is more aggressive, combining more intense chemotherapy regimens with craniospinal radiation therapy. Survival rates among patients with these tumors are markedly lower than those noted in patients with germinoma, ranging from 40-70% at 5 yr. Trials have shown the benefit of the use of high doses of chemotherapy with peripheral blood stem cell rescue.

Tumors of the Brainstem

Tumors of the brainstem are a heterogeneous group of tumors that account for 10-15% of childhood primary CNS tumors. Outcome depends on tumor location, imaging characteristics, and the patient's clinical status. Patients with these tumors may present with motor weakness, cranial nerve dysfunction, cerebellar dysfunction, and/or signs of increased ICP. On the basis of MRI evaluation and clinical findings, tumors of the brainstem can be classified into 4 types: focal (5-10% of patients); dorsally exophytic (5-10%); cervicomedullary (5-10%); and diffuse intrinsic (70-85%) (Fig. 497-8). Surgical resection is the primary treatment approach for focal and dorsally exophytic tumors and leads to a favorable outcome. Histologically, these 2 groups usually are low-grade gliomas. Cervicomedullary tumors, owing to their location, may not be amenable to surgical resection but are sensitive to radiation therapy. Diffuse intrinsic tumors, characterized by the diffuse infiltrating pontine glioma, are associated with a very poor outcome independent of histologic diagnosis. These tumors are not amenable to surgical resection. Biopsy in children in whom MRI shows a diffuse intrinsic tumor is controversial and is not recommended unless there is suspicion of another diagnosis, such as infection, vascular malformation, multiple sclerosis or other disorder of myelination, or metastatic tumor. These diagnoses are much more common in adults. The standard approach for treatment of diffuse infiltrating pontine gliomas has been radiation therapy, and median survival with this treatment is 12 mo, at best. Use of chemotherapy, including high-dose chemotherapy with peripheral blood stem cell rescue, has not yet been of survival benefit in this group of patients. Current approaches include evaluation of investigational agents alone or in combination with radiation therapy, similar to approaches being pursued in patients with malignant gliomas.

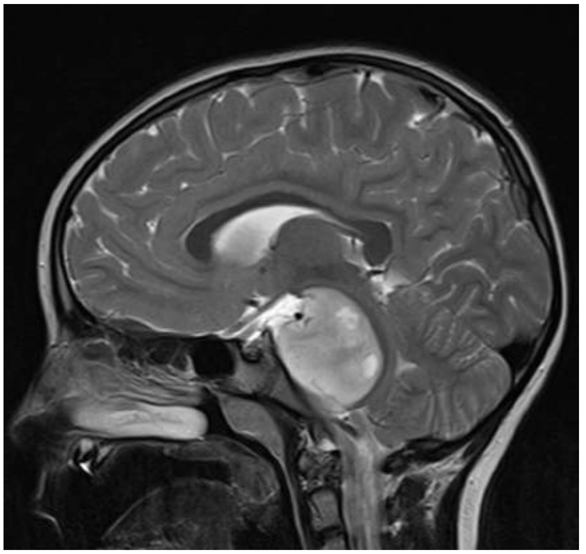

Figure 497-8 T2-weighted sagittal MR image of a diffuse infiltrating pontine glioma in a 5 yr old girl presenting with headaches, left facial droop, and lethargy.

Metastatic Tumors

Metastatic spread of other childhood malignancies to the brain is uncommon. Childhood acute lymphoblastic leukemia and non-Hodgkin lymphoma can spread to the leptomeninges, causing symptoms of communicating hydrocephalus. **Chloromas,** which are collections of myeloid leukemia cells, can occur throughout the neuraxis. Rarely, brain parenchymal metastases occur from lymphoma, neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, osteosarcoma, and clear cell sarcoma of the kidney. Therapeutic approaches are based on the specific histologic diagnosis and may incorporate radiation therapy, intrathecal administration of chemotherapy, and/or systemic administration of chemotherapy. Medulloblastoma is the childhood brain tumor that most commonly metastasizes extraneurally. Less commonly, extraneural metastases from malignant glioma, PNET, and ependymoma can occur. Ventriculoperitoneal shunts have been known to allow extraneural metastases, primarily within the peritoneal cavity but also systemically.

COMPLICATIONS AND LONG-TERM MANAGEMENT

Data from the National Cancer Institute Surveillance, Epidemiology and End Results Program indicate that more than 70% of patients with childhood brain tumors will be long-term survivors. At least 50% of these survivors will experience chronic problems as a direct result of their tumors and treatment. These problems include chronic neurologic deficits such as focal motor and sensory abnormalities, seizure disorders, neurocognitive deficits (e.g., developmental delays, learning disabilities), and neuroendocrine deficiencies (e.g., hypothyroidism, growth failure, delay or absence of puberty). These patients are also at significant risk for secondary malignancies. Supportive multidisciplinary interventions for children with brain tumors both during and after therapy may help improve the ultimate outcome. Optimal seizure management, physical therapy, endocrine management with timely growth hormone and thyroid replacement therapy, tailored educational programs, and vocational interventions may enhance the childhood brain tumor survivor's quality of life.

Chapter 498

Neuroblastoma

Peter E. Zage and Joann L. Ater

Neuroblastomas are embryonal cancers of the peripheral sympathetic nervous system with heterogeneous clinical presentation and course, ranging from tumors that undergo spontaneous regression to very aggressive tumors unresponsive to very intensive multimodal therapy. The causes of most cases remain unknown, and although significant advances have been made in the treatment of children with these tumors, the outcomes for aggressive forms of neuroblastoma remain poor.

EPIDEMIOLOGY

Neuroblastoma is the most common extracranial solid tumor in children and the most commonly diagnosed malignancy in infants. Approximately 600 new cases are diagnosed each year in the United States, accounting for 8-10% of childhood malignancies and one third of cancers in infants. Neuroblastoma accounts for >15% of the mortality from cancer in children. The median age of children at diagnosis of neuroblastoma is 22 mo, and 90% of cases are diagnosed by 5 yr of age. The incidence is slightly higher in boys and in whites.

PATHOLOGY

Neuroblastoma tumors, which are derived from primordial neural crest cells, form a spectrum with variable degrees of neural differentiation, ranging from tumors with primarily undifferentiated small round cells (neuroblastoma) to tumors consisting of mature and maturing Schwannian stroma with ganglion cells (ganglioneuroblastoma or ganglioneuroma). The tumors may resemble other **small round blue cell tumors,** such as rhabdomyosarcoma, Ewing sarcoma, and non-Hodgkin lymphoma. The prognosis of children with neuroblastoma varies with the histologic features of the tumor, and prognostic factors include the presence and amount of Schwannian stroma, the degree of tumor cell differentiation, and the mitosis-karyorrhexis index.

PATHOGENESIS

The etiology of neuroblastoma in most cases remains unknown. Familial neuroblastoma accounts for 1-2% of all cases, is associated with a younger age at diagnosis, and is linked to mutations in the *PHOX2B* and *ALK* genes. The *BARD1* gene has also been identified as a major genetic contributor to neuroblastoma risk. Neuroblastoma is associated with other neural crest disorders, including Hirschsprung disease, central hypoventilation syndrome, and neurofibromatosis type I, and potentially congenital cardiovascular malformations (Table 498-1). Children with Beckwith-Wiedemann syndrome and hemihypertrophy also have a higher incidence of neuroblastoma. Increased incidence of neuroblastoma is associated with some maternal and paternal occupational chemical exposures, farming, and work related to electronics, although no single environmental exposure has been shown to directly cause neuroblastoma.

Genetic characteristics of neuroblastoma tumors that are of prognostic importance include amplification of the *MYCN* (*N-myc*) proto-oncogene and tumor cell DNA content, or ploidy (Tables 498-2 to 498-4). Amplification of *MYCN* is strongly associated with advanced tumor stage and poor outcomes. Hyperdiploidy confers better prognosis if the child is younger than 1 yr of age at diagnosis. Other chromosomal abnormalities, including loss of heterozygosity of 1p, 11q, and 14q, and gain of 17q, are commonly found in neuroblastoma tumors and are also associated with worse outcomes. In addition, many other biologic factors are associated with neuroblastoma outcomes, including tumor vascularity and the expression levels of nerve growth factor receptors (TrkA, TrkB), ferritin, lactate dehydrogenase, ganglioside GD2, neuropeptide Y, chromogranin A, CD44, multidrug resistance–associated protein, and telomerase. These factors and many others are under investigation in clinical trials to determine whether they can be used to reduce therapy for children predicted to fare well with minimal therapy and to intensify therapy for those predicted to be at high risk for relapse.

CLINICAL MANIFESTATIONS

Neuroblastoma may develop at any site of sympathetic nervous system tissue. Approximately half of neuroblastoma tumors arise in the adrenal glands, and most of the remainder originate in the paraspinal sympathetic ganglia. Metastatic spread, which is more common in children older than 1 yr of age at diagnosis, occurs via local invasion or distant hematogenous or lymphatic routes. The most common sites of metastasis are the regional or distant lymph nodes, long bones and skull, bone marrow, liver, and skin. Lung and brain metastases are rare, occurring in >3% of cases.

The signs and symptoms of neuroblastoma reflect the tumor site and extent of disease, and the symptoms of neuroblastoma can mimic many other disorders, a fact that can result in a delayed diagnosis. Metastatic disease can cause a variety of signs and symptoms, including fever, irritability, failure to thrive, bone pain, cytopenias, bluish subcutaneous nodules, orbital proptosis, and periorbital ecchymoses (Fig. 498-1). Localized disease can manifest as an asymptomatic mass or can cause

Table 498-1 Syndromes Associated with Neuroblastoma

EPONYM	FEATURES
Pepper syndrome	Massive involvement of the liver with metastatic disease with or without respiratory distress.
Horner syndrome	Unilateral ptosis, myosis, and anhidrosis associated with a thoracic or cervical primary tumor. Symptoms do not resolve with tumor resection.
Hutchinson syndrome	Limping and irritability in young child associated with bone and bone marrow metastases.
Opsoclonus-myoclonus-ataxia syndrome	Myoclonic jerking and random conjugate eye movements with or without cerebellar ataxia. Often associated with a biologically favorable and differentiated tumor. The condition is likely immune mediated, may not resolve with tumor removal, and often exhibits progressive neuropsychologic sequelae.
Kerner-Morrison syndrome	Intractable secretory diarrhea due to tumor secretion of vasointestinal peptides. Tumors are generally biologically favorable.
Neurocristopathy syndrome	Neuroblastoma associated with other neural crest disorders, including congenital hypoventilation syndrome or Hirschsprung disease. Germline mutations in the paired homeobox gene *PHOX2B* have been identified in a subset of patients with this disease.
ROHHAD	Approximately 40% may have neural crest-derived tumors. Obesity and neurologic issues may be part of a paraneoplastic syndrome.

ROHHAD, rapid-onset obesity, hypothalamic dysfunction, hypoventilation, autonomic dysregulation.

Table 498-3 International Neuroblastoma Staging System

STAGE	DEFINITION	INCIDENCE (%)	SURVIVAL AT 5 YR* (%)
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive)	5	≥90
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically	10	70-80
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes must be negative microscopically	10	70-80
3	Unresectable unilateral tumor infiltrating across the midline,† with or without regional lymph node involvement; *or* localized unilateral tumor with contralateral regional lymph node involvement; *or* midline tumor with bilateral extension by infiltration (resectable) or by lymph node involvement	25	40-70
4	Any primary tumor with dissemination to distant lymph nodes; bone, bone marrow, liver, skin, and other organs (except as defined for stage 4S)	60	85-90 if age at diagnosis is <18 mo 30-40 if age at diagnosis is >18 mo
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, and bone marrow‡ (limited to infants <1 yr of age)	5	>80

*Survival is influenced by other characteristics, such as *MYCN* amplification. Percentages are approximate.
†The *midline* is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the other side of the vertebral column.
‡Marrow involvement in stage 4S should be minimal (i.e., <10% of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate). More extensive marrow involvement would be considered stage 4. Results of the metaiodobenzylguanidine (MIBG) scan (if performed) should be negative in the marrow.
Modified from Kliegman RM, Marcdante KJ, Jenson HB, et al, editors: Nelson essentials of pediatrics, *ed 5, Philadelphia, 2006, WB Saunders, p. 746; and Brodeur GM, Pritchard J, Berthold F, et al: Revisions of the international criteria for neuroblastoma diagnosis, staging, and response to treatment,* J Clin Oncol *11:1466–1477, 1993.*

symptoms because of the mass itself, including spinal cord compression, bowel obstruction, and superior vena cava syndrome.

Children with neuroblastoma can also present with neurologic signs and symptoms. Neuroblastoma originating in the superior cervical ganglion can result in **Horner syndrome.** Paraspinal neuroblastoma tumors can invade the neural foramina, causing spinal cord and nerve root compression. Neuroblastoma can also be associated with a paraneoplastic syndrome of autoimmune origin, termed *opsoclonus–myoclonus–ataxia syndrome,* in which patients experience rapid, uncontrollable jerking eye and body movements, poor coordination,

Table 498-4 Phenotypic and Genetic Features of Neuroblastoma, Treatment, and Survival According to Prognostic Category

VARIABLE	PROGNOSTIC CATEGORY*			
	Low Risk	**Intermediate Risk**	**High Risk**	**Tumor Stage 4S**
Pattern of disease	Localized tumor	Localized tumor with locoregional lymph node extension; metastases to bone marrow and bone in infants	Metastases to bone marrow and bone (except in infants)	Metastases to liver and skin (with minimal bone marrow involvement) in infants
Tumor genomics	Whole-chromosome gains	Whole-chromosome gains	Segmental chromosomal aberrations	Whole-chromosome gains
Treatment	Surgery†	Moderate-intensity chemotherapy; surgery†	Dose-intensive chemotherapy, surgery, and external-beam radiotherapy to primary tumor and resistant metastatic sites; myeloablative chemotherapy with autologous hematopoietic stem cell rescue; isotretinoin with anti–ganglioside GD2 immunotherapy	Supportive care‡
Survival rate	>98%	90-95%	40-50%	>90%

*Patients are assigned to prognostic groups according to risk, as described by the Children's Oncology Group, with the level of risk defining the likelihood of death from disease. Stage 4S disease is considered separately here because of the unique phenotype of favorable biologic features and relentless early progression but ultimately full and complete regression of the disease.

†The goal of surgery is to safely debulk the tumor mass and avoid damage to surrounding normal structures while also obtaining sufficient material for molecular diagnostic studies. Some localized tumors may spontaneously regress without surgery.

‡Low-dose chemotherapy or radiation therapy, or both, is used in patients with life-threatening hepatic involvement, especially in infants <2 mo of age, who are at much higher risk for life-threatening complications from massive hepatomegaly.

From Maris JM: Recent advances in neuroblastoma, N Engl J Med *362:2202–2210, 2010.*

Figure 498-1 Periorbital metastases of neuroblastoma with ecchymoses and proptosis.

and cognitive dysfunction. Some tumors produce catecholamines that can cause increased sweating and hypertension, and some release vasoactive intestinal peptide, causing a profound secretory diarrhea. Children with extensive tumors can also experience tumor lysis syndrome and disseminated intravascular coagulation. Infants younger than 1 yr of age also can present in unique fashion, termed *stage 4S,* with widespread subcutaneous tumor nodules, massive liver involvement, limited bone marrow disease, and a small primary tumor without bone involvement or other metastases.

DIAGNOSIS

Neuroblastoma is usually discovered as a mass or multiple masses on plain radiography, CT, or MRI (Fig. 498-2*A*). The mass often contains calcification and hemorrhage that can be appreciated on plain radiography or CT. Prenatal diagnosis of neuroblastoma on maternal ultrasound scans is sometimes possible. Tumor markers, including catecholamine metabolites homovanillic acid and vanillylmandelic acid, are elevated in the urine of approximately 95% of cases and help to confirm the diagnosis. A pathologic diagnosis is established from tumor tissue obtained by biopsy. Neuroblastoma can be diagnosed without a primary tumor biopsy if small round blue tumor cells are observed in bone marrow samples (Fig. 498-3) and the levels of vanillylmandelic acid or homovanillic acid are elevated in the urine.

Evaluations for metastatic disease should include CT or MRI of the chest and abdomen, bone scans to detect cortical bone involvement, and at least 2 independent bone marrow aspirations and biopsies to evaluate for marrow disease. **Iodine-123 metaiodobenzylguanidine (^{123}I-MIBG)** studies should be used when available to better define the extent of disease (see Fig. 498-2*B* and *C*). MRI of the spine should be performed in cases with suspected or potential spinal cord compression, but imaging of the brain with either CT or MRI is not routinely performed unless dictated by the clinical presentation.

The **International Neuroblastoma Staging System (INSS)** is currently used to stage patients with neuroblastoma after initial surgical resection (see Table 498-3). INSS stage 1 tumors are confined to the organ or structure of origin and are completely resected. INSS stage 2 tumors extend beyond the structure of origin but not across the midline, either with (stage 2B) or without (stage 2A) ipsilateral lymph node involvement. INSS stage 3 tumors extend beyond the midline, with or without bilateral lymph node involvement, whereas INSS stage 4 tumors are disseminated, with metastases to bones, bone marrow, liver, distant lymph nodes, and other organs. INSS stage 4S refers to neuroblastoma in children younger than 1 yr of age with dissemination to liver, skin, and/or bone marrow without bone involvement and with a primary tumor that would otherwise be staged as INSS stage 1 or 2. A new International Neuroblastoma Risk Group Staging System was recently developed to allow for more effective comparisons of treatments and outcomes worldwide.

TREATMENT

Treatment strategies for neuroblastoma have changed dramatically over the past 20 yr, with significant reduction in treatment intensity for children who have localized low-risk tumors and with continued increased treatment intensity and addition of new agents for treatment of children who have high-risk neuroblastoma. The patient's age and tumor stage are combined with cytogenetic and molecular features of the tumor to determine the treatment risk group and estimated prognosis for each patient (see Tables 498-2 to 498-4). The usual treatment for children with low-risk neuroblastoma is surgery for stages 1 and 2 and observation for stage 4S with cure rates generally >90% without further therapy. Treatment with chemotherapy or radiation for the rare child with local recurrence can still be curative. Children with spinal cord compression at diagnosis also may require urgent treatment with chemotherapy, surgery, or radiation to avoid neurologic

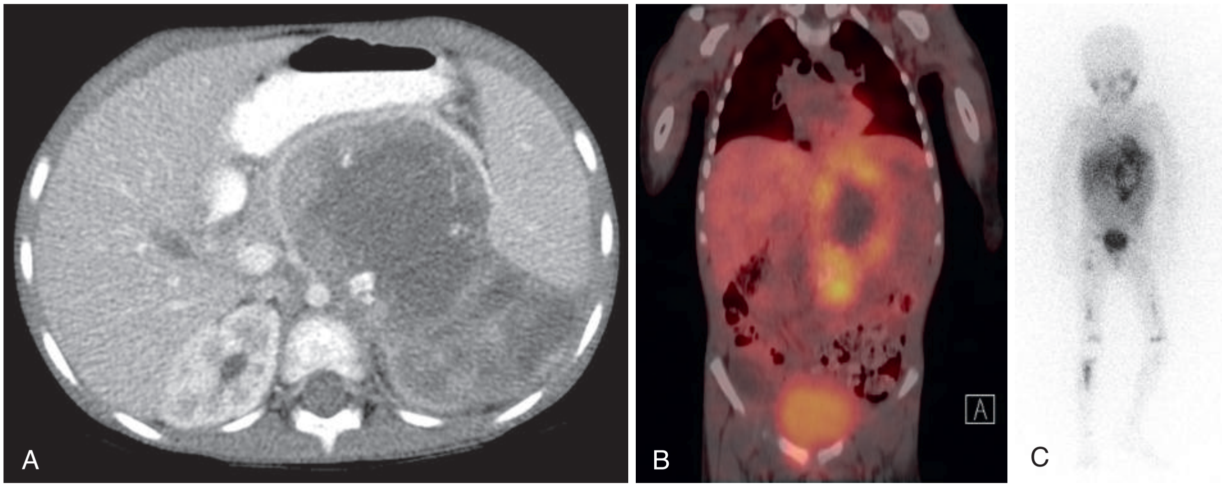

Figure 498-2 **A,** CT scan of an abdominal neuroblastoma with central necrosis at diagnosis. **B,** Coronal fused CT and metaiodobenzylguanidine (MIBG) image of same child with extensive retroperitoneal mass and central necrosis, probably an adrenal primary with extensive lymph node involvement. **C,** MIBG avid neuroblastoma with increased uptake of radiolabeled tracer can be detected in multiple sites of disease, including bone and soft tissue.

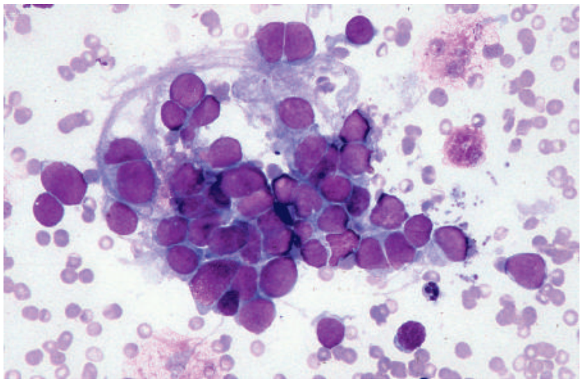

Figure 498-3 Neuroblastoma cells aspirated from the bone marrow. Clumps of cells often contain ≥3 cells with or without evidence of rosette formation. Rosettes of cells surrounding an inner mass of fibrillary material are characteristic of neuroblastoma.

damage. Stage 4S neuroblastomas have a very favorable prognosis, and many regress spontaneously without therapy. Chemotherapy or resection of the primary tumor does not improve survival rates, but for infants with massive liver involvement and respiratory compromise, small doses of cyclophosphamide or low-dose hepatic irradiation may alleviate symptoms. For children with stage 4S neuroblastoma who require treatment for symptoms, the survival rate is 81%.

Treatment of intermediate-risk neuroblastoma includes surgery, chemotherapy, and, in some cases, radiation therapy. The chemotherapy usually includes moderate doses of cisplatin or carboplatin, cyclophosphamide, etoposide, and doxorubicin given for several months. Radiation therapy is used for tumors with incomplete response to chemotherapy. Children with intermediate-risk neuroblastoma, including children with stage 3 disease and infants with stage 4 disease and favorable characteristics, have an excellent prognosis and >90% survival with this moderate treatment. In this intermediate-risk group, obtaining adequate diagnostic material for determination of the underlying biologic features of the tumor, such as the Shimada pathologic classification and *MYCN* gene amplification, is critical, so that children with unfavorable characteristics can receive more-aggressive treatment and those with favorable features can be spared excessive toxic therapy.

Children with high-risk neuroblastoma have long-term survival rates between 25% and 35% with current treatment that consists of intensive chemotherapy, high-dose chemotherapy with autologous stem cell rescue, surgery, radiation, and 13-*cis*-retinoic acid (isotretinoin, Accutane). Induction chemotherapy for children with high-risk neuroblastoma includes combinations of cyclophosphamide, topotecan, doxorubicin, vincristine, cisplatin, and etoposide. After completion of induction chemotherapy, resection of the residual primary tumor is followed by high-dose chemotherapy with autologous stem cell rescue and focal radiation therapy to tumor sites. A national cooperative group trial demonstrated significantly better survival with chemotherapy plus autologous stem cell rescue than with chemotherapy alone. The further addition of 13-*cis*-retinoic acid after autologous stem cell transplantation resulted in further improvements in survival rates. In addition, a national clinical trial has demonstrated an increase in short-term survival rates with the addition of the monoclonal antibody ch14.18, interleukin 2, and granulocyte-macrophage colony-stimulating factor to 13-*cis*-retinoic acid therapy.

Cases of high-risk neuroblastoma are associated with frequent relapses, and children with recurrent neuroblastoma have a <50% response rate to alternative chemotherapy regimens. New treatment strategies and agents are needed for children with both high-risk and recurrent neuroblastoma. Therapies currently under investigation include new chemotherapeutic agents and other novel therapies directed against critical intracellular signaling pathways, radiolabeled targeted agents (such as ^{131}I-MIBG), immunotherapy, and antitumor vaccines. Ongoing biologic studies of neuroblastoma will also hopefully lead to the identification of new molecular and genetic targets for therapy.

Chapter 499

Neoplasms of the Kidney

499.1 Wilms Tumor

Najat C. Daw, Vicki Huff, and Peter M. Anderson

Wilms tumor (WT), also known as nephroblastoma, is the most common primary malignant renal tumor of childhood; other renal tumors are very rare. It is the second most common malignant

abdominal tumor in childhood. The most common sites of metastases are the lungs, regional lymph nodes, and liver. Histologically, the classic WT is made up of varying proportions of blastemal, stromal, and epithelial cells, recapitulating stages of normal renal development. The treatment includes surgery and chemotherapy with or without radiotherapy. The use of multimodality treatment and multiinstitutional cooperative group trials has dramatically improved the cure rate of WT from <30% to approximately 90% (Table 499-1).

EPIDEMIOLOGY

WT accounts for 6% of pediatric malignancies and more than 95% of kidney tumors in children. In the United States, the incidence of WT is approximately 8 cases per 1 million children younger than 15 yr of age per year, and about 650 new cases are diagnosed each year. Approximately 75% of the cases occur in children younger than 5 yr with a peak incidence at 2-3 yr of age. It can arise in 1 or both kidneys; the incidence of bilateral WTs is 7%. Most cases are sporadic, but approximately 2% of patients have a family history. In 8-10% of patients, WT is observed in the context of hemihypertrophy, aniridia, genitourinary anomalies, and a variety of rare syndromes, including **Beckwith-Wiedemann syndrome** and **Denys-Drash syndrome** (Table 499-2). An earlier age of diagnosis and an increased incidence of bilateral disease are generally observed in syndromic and familial cases.

Table 499-1 Ten Yr Outcomes for Patients with Wilms Tumor Treated in the National Wilms Tumor Study IV

HISTOLOGY	STAGE	RECURRENCE-FREE SURVIVAL (%)	OVERALL SURVIVAL (%)
Favorable	I	91	96
Favorable	II	85	93
Favorable	III	84	89
Favorable	IV	75	81
Favorable	V	65	78
Anaplastic	I	69	82
Anaplastic	II-III	43	49
Anaplastic	IV	18	18

Table 499-2 Syndromes Associated with Wilms Tumor

SYNDROME	CLINICAL CHARACTERISTICS	GENETIC ANOMALIES
Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation (WAGR)	Aniridia, genitourinary abnormalities, mental retardation	Del 11p13 (*WT1* and *PAX6*)
Denys-Drash	Early-onset renal failure with renal mesangial sclerosis, male pseudohermaphroditism	*WT1* missense mutation
Beckwith-Wiedemann	Organomegaly (liver, kidney, adrenal, pancreas) macroglossia, omphalocele, hemihypertrophy	Unilateral paternal disomy, duplication of 11p15.5, loss of imprinting, mutation of *p57KIP57* Del 11p15.5 *IGF2* and *H19* imprinting control region

ETIOLOGY: GENETICS AND MOLECULAR BIOLOGY

WT is thought to be derived from incompletely differentiated renal mesenchyme, and tumors are typically composed of cells reminiscent of the undifferentiated and partially differentiated cells that normally arise from renal mesenchyme. Foci of benign, undifferentiated mesenchyme (nephrogenic rests) that persist abnormally in the kidney into postnatal life are observed in approximately 1% of children in the general population, but are present in up to 90% of children who have a family history of WT, develop bilateral tumors, or display features of WT-related syndromes. Nephrogenic rests usually regress or differentiate, but those that persist can become malignant.

To date genetic mutations have been detected, either individually or in combination, in a third of WTs. Mutations in *WT1*, a gene located at 11p13 and encoding a zinc finger transcription factor, are observed in 15-20% of tumors. These are homozygous and result in loss of *WT1* function. The majority of *WT1* mutations are somatic, result in loss of *WT1* function, and are present homozygously. However, germline *WT1* mutations are also observed, primarily in patients with WT-associated syndromes, or sometimes in patients with bilateral disease. In these instances, the wild-type allele present in the germline is mutated or lost in the tumor, resulting in loss of *WT1* function. Interestingly, nephrogenic rests assessed from patients heterozygous for a germline *WT1* mutation are homozygous for the *WT1* mutation, with additional somatic mutations being observed in the autologous tumors. The vast majority of *WT1* mutations are deletion/truncating mutations or missense mutations that affect amino acid residues critical for *WT1* function. Germline truncating mutations are usually associated with WT in the context of genitourinary anomalies or the WAGR (Wilms, aniridia, genitourinary anomalies, mental retardation) syndrome. Missense germline mutations are usually observed in children with Denys-Drash syndrome in which early-onset renal failure is observed.

Mutations in *CTNNB1*, encoding β-catenin, which acts as a major regulatory point in the wnt signaling pathway and also acts at the cytoplasmic membrane, are observed in approximately 15% of WTs, very often those that have sustained *WT1* mutations. *WTX*, a gene located on the X chromosome that encodes a protein that also plays a role in wnt pathway regulation, is mutated in approximately 20% of tumors. *CTNNB1* and *WTX* mutations are somatic. Somatic mutation of the p53 gene, *TP53*, is observed in approximately 5% of tumors and is associated with anaplastic tumor histology, a poor prognostic feature of WT.

In approximately 70% of tumors, loss of heterozygosity (usually copy number neutral) or loss of imprinting at imprinted loci at 11p15 is observed. This epigenetic alteration (the observation of which led to the designation of a "*WT2*" gene) occurs in tumors both with and without *WT1, CTNNB1*, or *WTX* mutations, and often results in biallelic expression of *IGF2*, a normally imprinted gene that encodes insulin-like growth factor 2, in addition to the loss of imprinting of other 11p15 genes. Families with Beckwith-Wiedemann syndrome, a somatic overgrowth syndrome in which predisposition to embryonal tumors (including WT) is observed, have been genetically linked to 11p15, and microdeletions within the *IGF2* imprinting control region are present in Beckwith-Wiedemann syndrome families in which WT is observed.

WT is occasionally observed in families with a predisposition to **pleuropulmonary blastoma**, and mutations in the *DICER1* gene, located at 14q31 and encoding a key protein in the generation of microRNAs, are observed in these families. However, outside the context of these families, *DICER1* mutations are rare in WTs.

A family history of WT is noted in approximately 2% of WT patients, and predisposition is inherited as an autosomal dominant trait with incomplete penetrance. Predisposition to other tumor types or other phenotypes are not observed in the vast majority of these families. *WT1* mutations are detected in <5% of families, and these *WT1*-related families are small, with only 2 affected individuals. Genetic linkage analyses of large WT families have localized predisposition genes to 19q and 17q, but neither gene has been identified yet. However, some

Table 499-3 Differential Diagnosis of Abdominal and Pelvic Tumors in Children

TUMOR	PATIENT AGE	CLINICAL SIGNS	LABORATORY FINDINGS
Wilms	Preschool	Unilateral flank mass, aniridia, hemihypertrophy	Hematuria, polycythemia, thrombocytosis, elevated partial thromboplastin time value
Neuroblastoma	Preschool	Gastrointestinal/genitourinary obstruction, raccoon eyes, myoclonus opsoclonus, diarrhea, skin nodules	Increased urinary vanillylmandelic acid, or homovanillic acid, or ferritin, stippled calcification in the mass
Non-Hodgkin lymphoma	>1 yr	Intussusception in patients >2 yr old	Increased lactic dehydrogenase, blood cytopenia from bone marrow involvement
Rhabdomyosarcoma	All	Gastrointestinal/genitourinary obstruction, abdominal pain, vaginal bleeding, paratesticular mass	Hypercalcemia, blood cytopenia from bone marrow involvement
Germ cell tumor/teratoma	Preschool, teenage	Girls: abdominal pain, vaginal bleeding Boys: testicular mass, new-onset hydrocele, sacrococcygeal mass/dimple	Increased human chorionic gonadotropin, increased α-fetoprotein
Hepatoblastoma	Birth-3 yr	Large firm liver	Increased α-fetoprotein
Hepatoma	School age, teenage	Large firm nodule, hepatitis B, cirrhosis	Increased α-fetoprotein

families carry neither of these mutations, suggesting that additional WT loci exist. Some families are not linked to either of these genomic regions, indicating that additional WT predisposition genes exist. Similarly, somatic alterations at 1q, 7p, 16q, chromosome 12, and other genomic regions are observed in some WTs and are thought to harbor genes important in WT development.

CLINICAL PRESENTATION

The most common initial clinical presentation for WT is the incidental discovery of an asymptomatic **abdominal mass** by parents while bathing or clothing an affected child or by a physician during a routine physical examination (Table 499-3). At presentation the mass can be quite large because retroperitoneal masses can grow unhampered by strict anatomic boundaries. Functional defects in paired organs like the kidney, with good functional reserve, are also unlikely to be detected early. **Hypertension** is present in approximately 25% of tumors at presentation and has been attributed to increased renin activity. **Abdominal pain, gross painless hematuria, and fever** are other frequent findings at diagnosis. Occasionally, rapid **abdominal enlargement and anemia** occur as a result of bleeding into the renal parenchyma or pelvis. WT thrombus extends into the inferior vena cava in 4-10% of patients, and rarely into the right atrium. Patients might also have microcytic anemia from iron deficiency or anemia of chronic disease, polycythemia, elevated platelet count, and acquired deficiency of von Willebrand factor or factor VII deficiency.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

An abdominal mass in a child should be considered malignant until diagnostic imaging, laboratory findings, and pathology can define its true nature (see Table 499-3). Imaging studies include plain abdominal radiography, abdominal ultrasonography, and CT of the abdomen to define the intrarenal origin of the mass and differentiate it from adrenal masses (e.g., neuroblastoma) and other masses in the abdomen. Abdominal ultrasonography helps differentiate solid from cystic masses. WT might show focal areas of necrosis or hemorrhage and hydronephrosis caused by obstruction of the renal pelvis by the tumor. Ultrasonography with Doppler imaging of renal veins and the inferior vena cava is a useful first study that not only can look for WT but also can evaluate the collecting system and demonstrate tumor thrombi in the renal veins and inferior vena cava.

CT (Fig. 499-1) is useful to define the extent of the disease, integrity of the contralateral kidney, and metastasis. MRI requires sedation in young children and is not routinely used; it may be helpful in defining an extensive tumor thrombus that extends up to the level of the hepatic veins or even into the right atrium, and to distinguish WT from nephrogenic rests. Chest CT is more sensitive than chest radiography to screen for pulmonary metastasis, and is preferably performed before surgery because effusions and atelectasis can confound the interpretation of postoperative imaging studies. A bone scan is performed if the histologic diagnosis confirms clear cell sarcoma of the kidney to look for bone metastasis. Brain imaging with CT or MRI is obtained in cases of clear cell sarcoma of the kidney or rhabdoid tumor of the kidney as these tumors can spread to the brain.

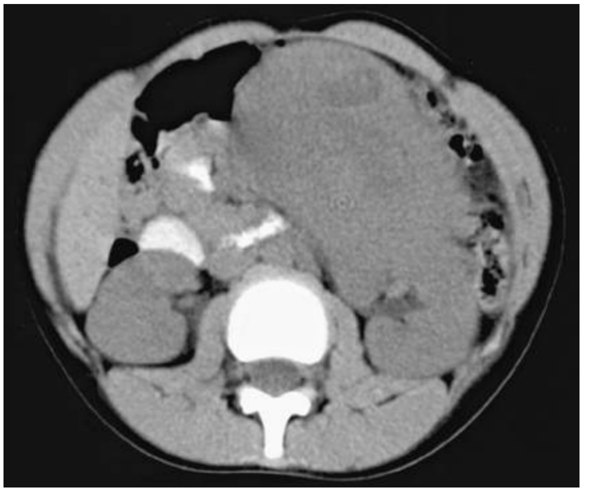

Figure 499-1 Abdominal CT scan showing a Wilms tumor arising from the left kidney. Because of their retroperitoneal location, such tumors can become very large (>10 cm) before clinical symptoms occur.

WT lesions are metabolically active and concentrate fluorodeoxyglucose. Regional spread and metastatic lesions can be visualized on positron emission tomography/CT scanning. The diagnosis is usually made by imaging studies and confirmed by histology at the time of nephrectomy. Although biopsy is a reliable diagnostic tool, it is discouraged as it results in disease upstaging. A core needle biopsy obtained via a posterior approach should be performed in cases of unusual presentation (older age, signs of infection, inflammation) or unusual imaging findings (significant adenopathy, no renal parenchyma seen, intratumoral calcification).

TREATMENT

There are 2 major schools of thought in the management of WT. The Children's Oncology Group, formerly National Wilms Tumor Study Group, advocates upfront surgery prior to initiating treatment. On the

Table 499-4	Staging of Wilms Tumor
Stage I	Tumor *confined to the kidney* and completely resected. Renal capsule or sinus vessels not involved. Tumor not ruptured or biopsied. Regional lymph nodes examined and negative.
Stage II	Tumor extends *beyond the kidney* but is completely resected with negative margins and lymph nodes. At least 1 of the following has occurred: (a) penetration of renal capsule, (b) invasion of renal sinus vessels.
Stage III	*Residual tumor* present following surgery confined to the abdomen, including gross or microscopic tumor; spillage of tumor preoperatively or intraoperatively; biopsy prior to nephrectomy, regional lymph node metastases; tumor implants on the peritoneal surface; extension of tumor thrombus into the inferior vena cava including thoracic vena cava and heart.
Stage IV	*Hematogenous metastases* (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdominopelvic region.
Stage V	*Bilateral* renal involvement by tumor.

other hand, the International Society of Pediatric Oncology recommends preoperative chemotherapy. Each approach has advantages and limitations but they have similar outcomes. Early surgery provides accurate diagnosis and staging, and can facilitate risk-adapted therapy. Preoperative chemotherapy can make surgery easier and reduces the risk of intraoperative tumor rupture and hemorrhage. Surgery entails a radical nephrectomy with meticulous dissection to avoid rupture of the tumor capsule and lymph node sampling despite the absence of abnormal nodes on preoperative imaging studies or intraoperative assessment. Partial nephrectomy is performed in patients with bilateral disease or with unilateral WT and a predisposing syndrome such as Denys-Drash and WAGR, so as to minimize the risk of future renal failure.

Prognostic factors for risk-adapted therapy include age, stage, tumor weight, and loss of heterozygosity at chromosomes 1p and 16q (Table 499-4). Histology plays a major role in risk stratification of WT. Absence of anaplasia is considered a favorable histologic finding. Presence of anaplasia is further classified as focal or diffuse, both of which are unfavorable histologic findings.

The Children's Oncology Group has specific drug dose and schedule recommendations for risk-adapted treatment of WT. Patients with favorable histologic findings of WT have a good outcome and are generally treated in the outpatient setting. Nephrectomy alone may be sufficient for patients younger than 2 yr of age with stage I disease and a tumor weighing <550 g. Patients with stages I and II disease receive chemotherapy with 2 drugs, vincristine and actinomycin D (also called dactinomycin), every 1-3 wk for a total of 18 wk (regimen EE4A). Patients with stage III or IV disease receive chemotherapy with 3 drugs (vincristine, doxorubicin, and actinomycin D) every 1-3 wk for a total of 24 wk (regimen DD4A) and radiation therapy. Patients with regional lymph node metastases, residual disease after surgery, or tumor rupture receive radiation therapy to the flank or abdomen, and those with lung metastases receive radiation therapy to the lungs. The presence of loss of heterozygosity at 1p and 16q confers an adverse prognosis, and deserves treatment intensification.

Anaplastic histology (focal and diffuse) accounts for approximately 11% of WT cases. Patients with diffuse anaplasia, in particular, have a poor outcome. They are treated with intensive chemotherapy regimens that include vincristine, cyclophosphamide, doxorubicin, etoposide, carboplatin, and ifosfamide, in addition to radiation therapy.

RECURRENT DISEASE

Approximately 15% of WT patients with favorable histology and 50% of those with anaplastic histology suffer relapse; most relapses occur early (within 2 yr of diagnosis). Factors associated with a favorable outcome after relapse include low stage (I/II) at diagnosis, treatment with vincristine and actinomycin D only, no prior radiotherapy, favorable histology, relapse to lung only, and interval from nephrectomy to relapse 12 mo or longer. Patients with recurrent WT who previously received only vincristine and actinomycin D had a 4 yr survival of approximately 80%, whereas those who previously received the 3 drug regimen of vincristine, actinomycin D, and doxorubicin had a 4 yr survival of only 50%. Other agents used to treat recurrent WT include doxorubicin, carboplatin, cyclophosphamide, ifosfamide, etoposide, and topotecan. Metachronous WT may not represent tumor relapse but instead may indicate development of a new tumor in the opposite kidney.

PROGNOSIS

Despite some adverse risk factors that decrease prognosis (metastases, unfavorable histology, recurrent disease, and loss of heterozygosity of both 1p and 16q), most children with WT have a very favorable prognosis. Overall, the survival of children with WT approaches 90%, with some prognostic factors (low stage, favorable histology, young age, low tumor weight) conferring even better outcomes.

LATE EFFECTS

Current strategies are successful with relatively few long-term effects of therapy. Late complications are a consequence of treatment type and intensity; the use of radiotherapy and anthracyclines increases the risk of these complications. Clinically significant late sequelae include musculoskeletal effects, cardiac toxicity, pulmonary disease, reproductive problems, renal dysfunction, and the development of second malignant neoplasms.

499.2 Other Pediatric Renal Tumors

Najat C. Daw, Vicki Huff, and Peter M. Anderson

MESOBLASTIC NEPHROMA

Mesoblastic nephroma is the most common solid renal tumor identified in the **neonatal period** and the most frequent benign renal tumor in childhood. It represents 3-10% of all pediatric renal tumors. Many cases are diagnosed with prenatal ultrasound and can manifest as polyhydramnios, hydrops, and premature delivery. Most of the patients are diagnosed before 3 mo of age, whereas WT is rarely diagnosed before 6 mo of age. Radical nephrectomy is the treatment of choice and may be sufficient by itself. Local recurrence is uncommon. Although rare, malignant variants do occur, marked by metastases to the lung, liver, heart, and brain.

CLEAR CELL SARCOMA OF THE KIDNEY

Clear cell sarcoma of the kidney is an uncommon renal neoplasm of childhood with approximately 20 new cases diagnosed each year in North America. Peak incidence is between 1 and 4 yr of age, usually presenting as an abdominal mass. Gene expression profiles of clear cell sarcoma of the kidney suggest the cell of origin to be a renal mesenchymal cell with neural markers. Bone is the most common site of distant metastasis followed by lung, abdomen, retroperitoneum, brain, and liver. Therefore, the staging work-up should include a bone scan. Early-stage disease has an excellent prognosis, especially with the addition of doxorubicin.

RHABDOID TUMOR OF THE KIDNEY

Malignant rhabdoid tumor of the kidney has rhabdomyoblast-like morphology. It is a rare but aggressive cancer. Hematuria is a common presenting feature. Both rhabdoid tumor of the kidney and central nervous system atypical teratoid rhabdoid tumors have deletions and mutations of the *hSNF5/INI1* gene and are considered to be related. Prognosis is poor with current therapeutic protocols. The 5 yr overall survival rate is <30%.

RENAL CELL CARCINOMA

Renal cell carcinoma (RCC) is rare in children, accounting for <5% of all renal tumors of childhood. Patients may present with frank hematuria, flank pain, and/or a palpable mass, although RCC can be asymptomatic and detected incidentally. It has a propensity to metastasize to the lungs, bone, liver, and brain. RCC can be associated with von Hippel–Lindau disease. Unlike the case for adult RCC, local lymph node involvement is not a poor prognostic indicator in pediatric RCC. Nephrectomy alone may be adequate for early-stage RCC.

Chapter 500
Soft Tissue Sarcomas
Carola A.S. Arndt

The annual incidence of soft tissue sarcomas is 8.4 cases per 1 million white children younger than 14 yr of age. Rhabdomyosarcoma accounts for more than 50% of soft tissue sarcomas. The prognosis most strongly correlates with age and extent of disease at diagnosis, primary tumor site and histology, and expression of the fusion protein, PAX-FOXO1.

RHABDOMYOSARCOMA
Epidemiology
The most common pediatric soft tissue sarcoma, rhabdomyosarcoma, accounts for approximately 3.5% of childhood cancers. These tumors may occur at virtually any anatomic site but are usually found in the head and neck (25%), orbit (9%), genitourinary tract (24%), and extremities (19%); retroperitoneal and other sites account for the remainder of primary sites. The incidence at each anatomic site is related to both patient age and tumor type. Extremity lesions are more likely to occur in older children and to have alveolar histology. Rhabdomyosarcoma occurs with increased frequency in patients with neurofibromatosis and other family cancer predisposition syndromes such as Li-Fraumeni syndrome.

Pathogenesis
Rhabdomyosarcoma is thought to arise from the same embryonic mesenchyme as striated skeletal muscle although a large percentage of these tumors arise in areas lacking skeletal muscle (e.g., bladder, prostate, vagina). On the basis of light microscopic appearance, it belongs to the general category of small round cell tumors that includes Ewing sarcoma, neuroblastoma, and non-Hodgkin lymphoma. Definitive diagnosis of a pathologic specimen requires immunohistochemical studies using antibodies to skeletal muscle (desmin, muscle-specific actin, myogenin) and reverse transcription polymerase chain reaction or, in the case of alveolar tumors, fluorescent in situ hybridization for PAX-FOX01 transcript.

Determination of the specific histologic subtype is important in treatment planning and assessment of prognosis. There are 3 recognized histologic subtypes. The **embryonal type** accounts for approximately 60% of all cases and has an intermediate prognosis. The **botryoid type,** a variant of the embryonal form in which tumor cells and an edematous stroma project into a body cavity like a bunch of grapes, is found most often in the vagina, uterus, bladder, nasopharynx, and middle ear. The **alveolar type** accounts for approximately 25-40% of cases and often is characterized by the presence of PAX-FOXO1 fusion transcript. The tumor cells tend to grow in nests that often have cleft-like spaces resembling alveoli. Alveolar tumors occur most often in the trunk and extremities and carry the poorest prognosis. The **pleomorphic type** (adult form) is rare in childhood, accounting for <1% of cases.

Clinical Manifestations
The most common presenting feature of rhabdomyosarcoma is a mass that may or may not be painful. Symptoms are caused by displacement or obstruction of normal structures (Table 500-1). Origin in the nasopharynx may be associated with nasal congestion, mouth breathing, epistaxis, and difficulty with swallowing and chewing. Regional extension into the cranium can produce cranial nerve paralysis, blindness, and signs of increased intracranial pressure with headache and vomiting. When the tumor develops in the face or cheek, there may be swelling, pain, trismus, and, as extension occurs, paralysis of cranial nerves. Tumors in the neck can produce progressive swelling with neurologic symptoms after regional extension. Orbital primary tumors are usually diagnosed early in their course because of associated proptosis, periorbital edema, ptosis, change in visual acuity, and local pain. When the tumor arises in the middle ear, the most common early signs are pain, hearing loss, chronic otorrhea, or a mass in the ear canal; extensions of tumor produce cranial nerve paralysis and signs of an intracranial mass on the involved side. An unremitting croupy cough and progressive stridor can accompany rhabdomyosarcoma of the larynx. Because most of these signs and symptoms also are associated with common childhood conditions, clinicians must be alert to the possibility of tumor.

Rhabdomyosarcoma of the trunk or extremities often is first noticed after trauma and initially may be regarded as a hematoma. If the swelling does not resolve or increases, malignancy should be suspected. Involvement of the genitourinary tract can produce hematuria, obstruction of the lower urinary tract, recurrent urinary tract infections, incontinence, or a mass detectable on abdominal or rectal examination. Paratesticular tumor usually manifests as a painless, rapidly growing mass in the scrotum. Vaginal rhabdomyosarcoma may manifest as a grape-like mass of tumor tissue bulging through the vaginal orifice, known as **sarcoma botryoides**, and can cause urinary tract or large bowel symptoms. Vaginal bleeding or obstruction of the urethra or rectum may occur. Similar findings can be noted with uterine primaries.

Table 500-1 Staging System for Rhabdomyosarcoma

STAGE	SITE	T STAGE	SIZE	NODE STATUS	METASTASIS
1	Favorable	T1 or T2	a or b	N0 or N1 or Nx	M0
2	Unfavorable	T1 or T2	a	N0 or Nx	M0
3	Unfavorable	T1 or T2	a b	N1 N0 or N1 or Nx	M0
4	Any	T1 or T2	a or b	N0 or N1 or Nx	M1

T1, confined to anatomic site of origin; T2, extension and/or fixative to surrounding tissue.
Size: a, <5 cm in diameter; b, ≥5 cm in diameter.
Nodes: N0, regional nodes not involved; N1, regional nodes involved; Nx, regional node status unknown.
Metastases: M0, no distant metastases; M1, metastases present (includes positive cytology in CSF, pleural, or peritoneal fluid).

Table 500-2 Risk Groups and Outcome for Rhabdomyosarcoma, Children's Oncology Group

RISK GROUP	STAGE/GROUP	HISTOLOGY	LONG-TERM EFS
Low, subset 1	Stage 1, Groups I-II Stage 1, Group III (orbit) Stage 2, Groups I-II	Embryonal	85-95%
Low, subset 2	Stage 1, Group III (nonorbit) Stage 3, Groups I-II	Embryonal	70-85%
Intermediate	Stage 2-3, Group III Stage 1-3, Groups I-III	Embryonal Alveolar	73% 65%
High	Stage 4, Group IV Stage 4, Group IV	Embryonal Alveolar	35% 15%

From Hawkins DS, Spunt SL, Skapek SX: Children's Oncology Group's 2013 blueprint for research: soft tissue sarcomas. Pediatr Blood Cancer *60:1001–1008, 2013, Table I, p. 1002.*

Tumors in any location may disseminate early and cause symptoms of pain or respiratory distress associated with pulmonary metastases. Extensive bone involvement can produce symptomatic hypercalcemia. In such cases, it may be difficult to identify the primary lesion.

Diagnosis

Early diagnosis of rhabdomyosarcoma requires a high index of suspicion. The microscopic appearance is that of a small, round, blue cell tumor. Neuroblastoma, lymphoma, and Ewing sarcoma also are **small, round, blue cell tumors** from which suspected rhabdomyosarcomas must be differentiated. The differential diagnosis depends on the site of presentation. Definitive diagnosis is established by biopsy, microscopic appearance, and results of immunohistochemical stains and analysis of PAX/FOXO1 expression. A lesion in an extremity may be thought to be a hematoma or hemangioma; an orbital lesion resulting in proptosis may be treated as an orbital cellulitis; or bladder-obstructive symptoms may be missed. Adolescents may ignore or be embarrassed to mention paratesticular lesions for a long time. Unfortunately, several months often elapse between the initial symptoms and biopsy. Diagnostic procedures are determined mainly by the area of involvement. CT or MRI is necessary for evaluation of the primary tumor site. With signs and symptoms in the head and neck area, radiographs should be examined for evidence of a tumor mass and for indications of bony erosion. MRI should be performed to identify intracranial extension or meningeal involvement and also to reveal bony involvement or erosion at the base of the skull. For abdominal and pelvic tumors, CT with a contrast agent or MRI can help delineate the tumor (Fig. 500-1). A radionuclide bone scan, chest CT, and bilateral bone marrow aspiration and biopsy should be performed to evaluate the patient for the presence of metastatic disease and to plan treatment. Fluorodeoxyglucose positron emission tomography is being used more frequently to enhance staging. The most critical element of the diagnostic work-up is examination of tumor tissue, which includes the use of special histochemical stains and immunostains. Molecular genetics is important to detect fusion transcripts present in alveolar rhabdomyosarcoma (PAX-FOX1). Lymph nodes also should be sampled for the presence of disease spread, especially in tumors of the extremities and in boys older than 10 yr of age with paratesticular tumors.

Treatment

Treatment is multidisciplinary and includes the pediatric oncologist, pediatric surgeon or other surgical subspecialist, and most often radiation oncologist. Only if the tumor is able to be completely resected, with negative margins, without loss of function or major cosmetic deformity should this be attempted initially. Unfortunately, most rhabdomyosarcomas are not completely resectable at initial diagnosis. Treatment is based on risk classification of the tumor, which is determined by the stage of tumor, the tumor histology, and the amount of tumor that was surgically resected prior to chemotherapy ("surgical group"). Stage is dependent on primary site (favorable vs unfavorable), tumor invasiveness (T1 or T2), lymph node status, tumor size, and presence of metastasis. Favorable sites include female genital, paratesticular, and head and neck (nonparameningeal) regions; all other sites are considered unfavorable. Table 500-1 shows the Children's Oncology Group staging system for rhabdomyosarcoma.

Patients should be offered enrollment in clinical trials. Table 500-2 shows current risk stratification and outcome based on results of recent studies. Patients with low-risk disease can be cured with minimal therapy consisting of vincristine and of actinomycin with or without lower doses of cyclophosphamide; radiation therapy can be used in the case of residual disease after initial surgery. Treatment for patients with intermediate-risk disease consists of vincristine, actinomycin, and cyclophosphamide along with radiation. Clinical trials in North

Table 500-3 Features of Most Common Types of Nonrhabdomyosarcoma Soft Tissue Sarcomas

TISSUE TYPE	TUMOR	NATURAL HISTORY AND BIOLOGY
Adipose	Liposarcoma	A very rare tumor. Usually arises in the extremities or retroperitoneum; associated with a nonrandom translocation, t(12;16)(q13;p11). Tends to be locally invasive and rarely metastasizes; wide local excision is the treatment of choice. The role of radiation therapy and chemotherapy in treating gross residual or metastatic disease is not established.
Fibrous	Fibrosarcoma	Most common soft tissue sarcoma in children younger than 1 yr. Congenital fibrosarcoma is a low-grade malignancy that commonly arises in the extremities or trunk and rarely metastasizes. Surgical excision is treatment of choice; dramatic responses to preoperative chemotherapy may occur. In children older than 4 yr, the natural history is similar to that in adults (a 5 yr survival rate of 60%); wide surgical excision and preoperative chemotherapy are commonly used. Associated with t(12;15)(p13;q25) or trisomy 11, also +8, +17, +20.
	Malignant fibrous histiocytoma	Most commonly arises in the trunk and extremities, deep in the subcutaneous layer. Histologically subdivided into storiform, giant cell, myxoid, and angiomatoid variants. The angiomatoid type tends to affect younger patients and is curable with surgical resection alone. Wide surgical excision is the treatment of choice. Chemotherapy has produced objective tumor regressions.
Vascular	Hemangiopericytoma	Often arises in the lower extremities or retroperitoneum; may manifest as hypoglycemia and hypophosphatemic rickets. Both benign and malignant histology. Nonrandom translocations t(12;19)(q13;q13) and t(13;22)(q22;q13.3) have been described. Complete surgical excision is the treatment of choice. Chemotherapy and radiation therapy may produce responses.
	Angiosarcoma	Rare in children; 33% arise in skin, 25% in soft tissue, and 25% in liver, breast, or bone. Associated with chronic lymphedema and exposure to vinyl chloride in adults. Survival rate is poor (12% at 5 yr) despite some responses to chemotherapy/radiation therapy.
	Hemangioendothelioma	Can occur in soft tissue, liver, and lung. Localized lesions have a favorable outcome; lesions in lung and liver often are multifocal and have a poor prognosis.
Peripheral nerves	Neurofibrosarcoma	Also known as the malignant peripheral nerve sheath tumor. Develops in up to 16% of patients with neurofibromatosis type 1 (NF1); almost 50% occur in patients with NF1. Deletions of chromosome 22q11-q13 or 17q11 and p53 mutations have been reported. Commonly arises in trunk and extremities and is usually locally invasive. Complete surgical excision is necessary for survival; response to chemotherapy is suboptimal.
Synovium	Synovial sarcoma	The most common nonrhabdomyosarcoma soft tissue sarcoma in some series. Often manifesting in the 3rd decade, but 33% of patients are younger than age 20 yr. Typically arises around the knee or thigh and is characterized by a nonrandom translocation t(X;18)(p11;q11). Wide surgical excision is necessary. Radiation therapy is effective in microscopic residual disease, and ifosfamide-based therapy is active in advanced disease.
Unknown	Alveolar soft part sarcoma	Slow-growing tumor; tends to recur or to metastasize to lung and brain years after diagnosis. Often arises in the extremities and head and neck.
Smooth muscle	Leiomyosarcoma	Often arises in the gastrointestinal tract and may be associated with a t(12;14)(q14;q23) translocation. Associated with Epstein-Barr virus in immunodeficiency syndromes (including AIDS). Complete surgical excision is the treatment of choice.

America are investigating the role of topoisomerase inhibitors in this group of patients. For patients with high-risk disease, newer approaches using intensive multiagent chemotherapy along with biologic agents are being investigated.

Prognosis

Prognostic factors include age, stage, histology, and primary site. Among patients with resectable tumor and favorable histology, 80-90% have prolonged disease-free survival. Unresectable tumor localized to certain favorable sites, such as the orbit, also has a high likelihood of cure. Approximately 65-70% of patients with incompletely resected tumor also achieve long-term disease-free survival. Patients with disseminated disease have a poor prognosis; only approximately 50% achieve remission, and fewer than 50% of these are cured. Older children have a poorer prognosis than younger children. For all patients, surveillance for late effects of cancer treatment is extremely important. Some examples of late effects include infertility from cyclophosphamide, late effects in the radiation field such as bladder dysfunction, infertility, cataracts, impaired bone growth, and secondary malignancies.

OTHER SOFT TISSUE SARCOMAS

The nonrhabdomyosarcoma soft tissue sarcomas constitute a heterogeneous group of tumors that account for 3% of all childhood malignancies (Table 500-3). Because they are relatively rare in children, much of the information about their natural history and treatment has been derived from studies in adult patients. In children, the median age at diagnosis is 12 yr, with a male : female ratio of 2.3 : 1. These tumors commonly arise in the trunk or lower extremities. The most common histologic types are synovial sarcoma (42%), fibrosarcoma (13%), malignant fibrous histiocytoma (12%), and neurogenic tumors (10%). Molecular genetic studies often prove useful in diagnosis, because several of these tumors have characteristic chromosomal translocations. Tumor size, stage (clinical group), invasiveness, and histologic grade correlate with survival.

Surgery remains the mainstay of therapy, but a careful search for lung and bone metastases should be undertaken before surgical excision. Chemotherapy and radiation therapy should be considered for large, high-grade, and unresectable tumors. The role of chemotherapy for nonrhabdomyosarcoma soft tissue sarcomas is not as well defined as for rhabdomyosarcoma. Patients with unresectable or metastatic disease are treated with multiagent chemotherapy in addition to irradiation and/or surgery. Patients with completely resected small (<5 cm) tumors are generally treated with surgery alone and can be expected to have an excellent outcome regardless of whether the tumor is high or low grade.

Chapter 501
Neoplasms of Bone

501.1 Malignant Tumors of Bone

Carola A.S. Arndt

The annual incidence of malignant bone tumors in the United States is approximately 7 cases per 1 million white children younger than 14 yr of age, with a slightly lower incidence in African-American children. Osteosarcoma is the most common primary malignant bone tumor in children and adolescents, followed by Ewing sarcoma (Table 501-1; Fig. 501-1). In children younger than 10 yr of age, Ewing sarcoma is more common than osteosarcoma. Both tumor types are most likely to occur in the second decade of life.

OSTEOSARCOMA

Epidemiology

The annual incidence of osteosarcoma in the United States is 5.6 cases per 1 million children younger than 15 yr of age. The highest risk period for development of osteosarcoma is during the adolescent growth spurt, suggesting an association between rapid bone growth and malignant transformation. Patients with osteosarcoma are taller than their peers of similar age.

Pathogenesis

Although the cause of osteosarcoma is unknown, certain genetic or acquired conditions predispose patients to development of osteosarcoma. Patients with **hereditary retinoblastoma** have a significantly increased risk for development of osteosarcoma. The sites of osteosarcoma in these patients were initially thought to be only in previously irradiated areas, but later studies show them to arise in sites far from the original retinoblastoma radiation field. Predisposition to development of osteosarcoma in these patients may be related to loss of heterozygosity of the *RB* gene. Osteosarcoma also occurs in the **Li-Fraumeni syndrome**, which is a familial cancer syndrome associated with germline mutations of the *P53* gene. Kindreds with

Table 501-1 Comparison of Features of Osteosarcoma and the Ewing Family of Tumors

FEATURE	OSTEOSARCOMA	EWING FAMILY OF TUMORS
Age	Second decade	Second decade
Race	All races	Primarily whites
Sex (M:F)	1.5:1	1.5:1
Cell	Spindle cell–producing osteoid	Undifferentiated small round cell, probably of neural origin
Predisposition	Retinoblastoma, Li-Fraumeni syndrome, Paget disease, radiotherapy	None known
Site	Metaphyses of long bones	Diaphyses of long bones, flat bones
Presentation	Local pain and swelling; often, history of injury	Local pain and swelling; fever
Radiographic findings	Sclerotic destruction (less commonly lytic); sunburst pattern	Primarily lytic, multilaminar periosteal reaction ("onion-skinning")
Differential diagnosis	Ewing sarcoma, osteomyelitis	Osteomyelitis, eosinophilic granuloma, lymphoma, neuroblastoma, rhabdomyosarcoma
Metastasis	Lungs, bones	Lungs, bones
Treatment	Chemotherapy Ablative surgery of primary tumor	Chemotherapy Radiotherapy and/or surgery of primary tumor
Outcome	Without metastases, 70% cured; with metastases at diagnosis, ≤20% survival	Without metastases, 60% cured; with metastases at diagnosis, 20-30% survival

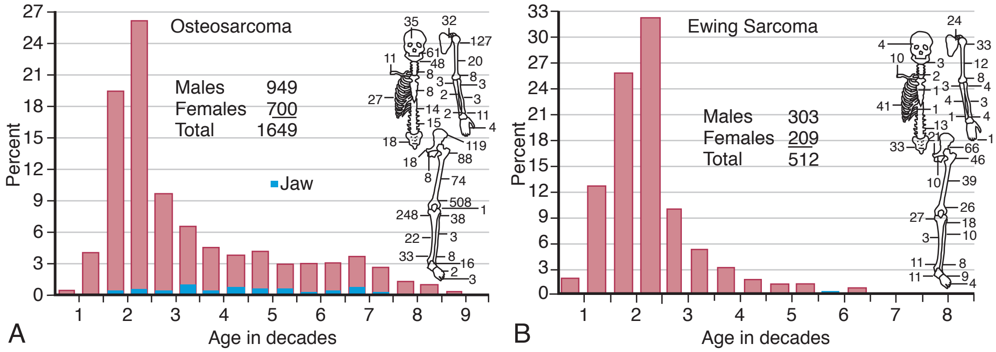

Figure 501-1 **A,** Age and skeletal distribution of 1,649 cases of osteosarcoma in the Mayo Clinic files. **B,** Age and skeletal distribution of 512 cases of Ewing sarcoma in the Mayo Clinic files. *(From Unni KK, editor:* Dahlin's bone tumors: general aspects and data on 11,087 cases, *ed 5, Philadelphia, 1996, Lippincott-Raven. Reprinted by permission of the Mayo Foundation.)*

Li-Fraumeni syndrome have a spectrum of malignancies in 1st-degree relatives, including carcinoma of the breast, soft tissue sarcomas, brain tumors, leukemia, adrenal cortical carcinoma, and other malignancies. **Rothmund-Thomson syndrome** is a rare syndrome associated with short stature, skin telangiectasia, small hands and feet, hypoplasticity or absence of the thumbs, and a high risk of osteosarcoma. Osteosarcoma also can be induced by irradiation for Ewing sarcoma, craniospinal irradiation for brain tumors, or high-dose irradiation for other malignancies. Other benign conditions that can be associated with malignant transformation to osteosarcoma include Paget disease, enchondromatosis, multiple hereditary exostoses, and fibrous dysplasia.

The pathologic diagnosis of osteosarcoma is made by demonstration of a highly malignant, pleomorphic, spindle cell neoplasm associated with the formation of malignant osteoid and bone. There are 4 pathologic subtypes of conventional high-grade osteosarcoma: osteoblastic, fibroblastic, chondroblastic, and telangiectatic. No significant differences in outcome are associated with the various subtypes, although the chondroblastic component of that subtype may not respond as well to chemotherapy. The role in prognosis of various genes such as drug resistance–related genes, tumor-suppressor genes, and genes related to apoptosis is being evaluated.

Telangiectatic osteosarcoma may be confused with aneurysmal bone cyst because of its lytic appearance on radiography. High-grade osteosarcoma typically arises in the diaphyseal region of long bones and invades the medullary cavity. It also may be associated with a soft tissue mass. Two variants of osteosarcoma, parosteal and periosteal osteosarcoma, should be distinguished from conventional osteosarcoma because of their characteristic clinical features. **Parosteal osteosarcoma** is a low-grade, well-differentiated tumor that does not invade the medullary cavity and most commonly is found in the posterior aspect of the distal femur. Surgical resection alone often is curative in this lesion, which has a low propensity for metastatic spread. **Periosteal osteosarcoma** is a rare variant that arises on the surface of the bone but has a higher rate of metastatic spread than the parosteal type and an intermediate prognosis.

Clinical Manifestations

Pain, limp, and swelling are the most common presenting manifestations of osteosarcoma. Because these tumors occur most often in active adolescents, initial complaints may be attributed to a sports injury or sprain; any bone or joint pain not responding to conservative therapy within a reasonable time should be investigated thoroughly. Additional clinical findings may include limitation of motion, joint effusion, tenderness, and warmth. Results of routine laboratory tests, such as a complete blood cell count and chemistry panel, are usually normal, although alkaline phosphatase or lactate dehydrogenase values may be elevated.

Diagnosis

Bone tumor should be suspected in a patient who presents with deep bone pain, often causing nighttime awakening, in whom there is a palpable mass and radiographs that demonstrate a lesion. The lesion may be mixed lytic and blastic in appearance, but new bone formation is usually visible. The classic radiographic appearance of osteosarcoma is the **sunburst pattern** (Fig. 501-2). When osteosarcoma is suspected, the patient should be referred to a center with experience in managing bone tumors. The biopsy and the surgery should be performed by the same surgeon so that the incisional biopsy site can be placed in a manner that will not compromise the ultimate limb salvage procedure. Tissue usually is obtained for molecular and biologic studies at the time of the initial biopsy. Before biopsy, MRI of the primary lesion and the entire bone should be performed to evaluate the tumor for its proximity to nerves and blood vessels, soft tissue and joint extension, and skip lesions. The metastatic work-up, which should be performed before biopsy, includes CT of the chest and radionuclide bone scanning to evaluate for lung and bone metastases, respectively. The **differential diagnosis** of a lytic bone lesion includes histiocytosis, Ewing sarcoma, lymphoma, and bone cyst.

Figure 501-2 Radiograph of an osteosarcoma of the femur with typical "sunburst" appearance of bone formation.

Treatment

With chemotherapy and surgery, the 5-yr disease-free survival rate of patients with nonmetastatic extremity osteosarcoma is 65-75%. Complete surgical resection of the tumor is important for cure. The current approach is to treat patients with preoperative chemotherapy in an attempt to facilitate limb salvage operations and to treat micrometastatic disease immediately. Up to 80% of patients are able to undergo limb salvage operations after initial chemotherapy. It is important to resume chemotherapy as soon as possible after surgery. Lung metastases present at diagnosis should be resected by thoracotomies at some time during the course of treatment. Active agents currently in use in multidrug chemotherapy regimens for conventional osteosarcoma include doxorubicin, cisplatin, methotrexate, and ifosfamide.

One of the most important prognostic factors in osteosarcoma is the histologic response to chemotherapy. An international cooperative group is performing a randomized trial of the postoperative addition of high-dose ifosfamide with etoposide to standard 3 drug therapy with cisplatin, doxorubicin, and methotrexate to improve the outcome of patients with a poor histologic response. Patients with a good histologic response were randomized to the addition of pegylated interferon-α2b. Results are anticipated in the near future. For patients with metastatic disease, a new approach is the addition of zoledronic acid, a bisphosphonate, to intensive chemotherapy, with results pending. After limb salvage surgery, intensive rehabilitation and physical therapy are necessary to ensure maximal functional outcome.

For patients who require amputation, early prosthetic fitting and gait training are essential to enable patients to resume normal activities as soon as possible. Before definitive surgery, patients with tumors on weight-bearing bones should be instructed to use crutches to avoid stressing the weakened bones and causing pathologic fracture. The role of chemotherapy in parosteal and periosteal osteosarcomas is not well defined, and chemotherapy is generally reserved for use in patients with tumors which have a high-grade microscopic appearance.

Prognosis

Surgical resection alone is curative only for patients with parosteal osteosarcoma. Conventional osteosarcoma requires multiagent chemotherapy. Up to 75% of patients with nonmetastatic extremity osteosarcoma are cured with current multiagent treatment protocols. The prognosis is not as favorable for patients with pelvic tumors as for those with primary tumors in the extremities. Twenty percent to 30% of patients who have limited numbers of pulmonary metastases also can be cured with aggressive chemotherapy and resection of lung nodules. Patients with bone metastases and those with widespread lung metastases have an extremely poor prognosis. Long-term follow-up of patients with osteosarcoma is important to monitor for late effects of chemotherapy, such as cardiotoxicity from anthracycline and hearing loss from cisplatin. Patients in whom late, isolated lung metastases develop may be cured with surgical resection of the metastatic lesions alone.

EWING SARCOMA

Epidemiology

The incidence of Ewing sarcoma in the United States is 2.1 cases per 1 million children. It is rare among African-American children. Ewing sarcoma, an undifferentiated sarcoma of bone, also may arise from soft tissue. The term **Ewing sarcoma family of tumors** refers to a group of small, round cell, undifferentiated tumors thought to be of neural crest origin that generally carry the same chromosomal translocation. This family of tumors includes Ewing sarcoma of bone and soft tissue and peripheral **primitive neuroectodermal tumor**. Treatment protocols for these tumors are the same whether the tumors arise in bone or soft tissue. Anatomic sites of primary tumors arising in bone are distributed evenly between the extremities and the central axis (pelvis, spine, and chest wall). Primary tumors arising in the chest wall are often referred to as **Askin tumors**.

Figure 501-3 Radiograph of tibial Ewing sarcoma showing periosteal elevation or "onion-skinning."

Pathogenesis

Immunohistochemical staining assists in the diagnosis of Ewing sarcoma to differentiate it from **small, round, blue cell tumors** such as lymphoma, rhabdomyosarcoma, and neuroblastoma. Histochemical stains may react positively with certain neural markers on tumor cells (neuron-specific enolase and S-100), especially in peripheral primitive neuroectodermal tumors. Reactivity with muscle markers (e.g., desmin, actin) is absent. Additionally, MIC-2 (CD99) staining is usually positive. A specific chromosomal translocation, t(11;22), or a variant thereof is found in most of the Ewing sarcoma family of tumors. Analysis for the translocation by FISH (fluorescent in situ hybridization) or polymerase chain reaction analysis for the chimeric fusion gene products EWS/FLI1 or EWS/ERG is utilized routinely in diagnosis.

Clinical Manifestations

Symptoms of Ewing sarcoma are similar to those of osteosarcoma. Pain, swelling, limitation of motion, and tenderness over the involved bone or soft tissue are common presenting symptoms. Patients with huge chest wall primary tumors may present with respiratory distress. Patients with paraspinal or vertebral primary tumors may present with symptoms of cord compression. Ewing sarcoma often is associated with **systemic manifestations**, such as fever and weight loss; patients may have undergone treatment for a presumptive diagnosis of osteomyelitis or a fever of unknown origin. Patients also may have a delay in diagnosis when their pain or swelling is attributed to a sports injury.

Diagnosis

The diagnosis of Ewing sarcoma should be suspected in a patient who presents with pain and swelling, with or without systemic symptoms, and with a radiographic appearance of a primarily lytic bone lesion with periosteal reaction, the characteristic **onion-skinning** (Fig. 501-3). A large, associated, soft tissue mass often is visualized on MRI or CT (Fig. 501-4). The **differential diagnosis** includes osteosarcoma, osteomyelitis, Langerhans cell histiocytosis, primary lymphoma of bone, metastatic neuroblastoma, or rhabdomyosarcoma in the case of a pure soft tissue lesion. Patients should be referred to a center with

Figure 501-4 MR image of tibial Ewing sarcoma showing a large associated soft tissue mass.

experience in managing bone tumors for evaluation and biopsy. Thorough evaluation for metastatic disease includes CT of the chest, radionuclide bone scan, and bone marrow aspiration and biopsy specimens from at least 2 sites. MRI of the tumor and the entire length of involved bone should be performed to determine the exact extension of the soft tissue and bony mass and the proximity of tumor to neurovascular structures. Fluorodeoxyglucose positron emission tomography scanning is being incorporated to enhance staging. Studies are also using fluorodeoxyglucose positron emission tomography to evaluate response to therapy.

To avoid compromising an ultimate potential for limb salvage by a poorly planned biopsy incision, the same surgeon should perform the biopsy and the surgical procedure. CT-guided biopsy of the lesion often provides diagnostic tissue. It is important to obtain adequate tissue for special stains and molecular studies.

Treatment

Tumors of the Ewing sarcoma family are best managed with a comprehensive multidisciplinary approach in which the surgeon, chemotherapist, and radiation oncologist plan therapy. Multiagent chemotherapy is important because it can shrink the tumor rapidly and is usually given before local control is attempted. In North America, standard chemotherapy for nonmetastatic Ewing sarcoma includes vincristine, doxorubicin, cyclophosphamide, etoposide, and ifosfamide. Chemotherapy usually causes dramatic shrinkage of the soft tissue mass and rapid, significant pain relief. The most recent published randomized study for patients with nonmetastatic Ewing sarcoma showed a statistically significantly better outcome when patients were treated on a 14 day schedule than on a 21 day schedule. Current studies are evaluating the addition of topoisomerase inhibitors to standard chemotherapy, and plans are under way to investigate the role of insulin-like growth factor receptor inhibitors for certain groups of patients. An international cooperative group trial is evaluating whether myeloablative chemotherapy and stem cell rescue is superior to chemotherapy with lung irradiation for patients with pulmonary metastases. Ewing sarcoma is considered a radiosensitive tumor, and local control may be achieved with irradiation or surgery. Radiation therapy is associated with a risk of radiation-induced second malignancies, especially osteosarcoma, as well as failure of bone growth in skeletally immature patients. Many centers prefer surgical resection, if possible, to achieve local control. It is important to provide the patient with crutches if the tumor is in a weight-bearing bone, to avoid a pathologic fracture before definitive local control. Chemotherapy should be resumed as soon as possible after surgery.

Prognosis

Patients with small, nonmetastatic, distally located extremity tumors have the best prognosis, with a cure rate of up to 75%. Patients with pelvic tumors have, until recently, had a much worse outcome. Patients with metastatic disease at diagnosis, especially bone or bone marrow metastases, have a poor prognosis, with <30% surviving long term. New approaches, such as very intensive chemotherapy with peripheral blood stem cell rescue, are being investigated in these patients.

Long-term follow-up of patients with Ewing sarcoma is important because of the potential for late effects of treatment, such as anthracycline cardiotoxicity; second malignancies, especially in the radiation field; and late relapses, even as long as 10 yr after initial diagnosis.

501.2 Benign Tumors and Tumor-Like Processes of Bone

Carola A.S. Arndt

Benign bone lesions in children are common in comparison with the relatively rare malignant neoplasms of bone. They present diagnostic challenges. Some, although histologically benign, can be life-threatening. No single element in the history or diagnostic test is sufficient to rule out malignancies or suggest the existence of non-neoplastic conditions. A broad range of diagnostic possibilities must be considered when the physician is confronted with an undiagnosed bone lesion. Benign lesions may be painless or painful, especially if a pathologic fracture is impending. Night pain that awakens a child suggests malignancy, but relief of such pain with aspirin is common with benign lesions such as osteoid osteomas. Rapidly enlarging lesions usually are associated with malignancy, but several benign lesions, such as aneurysmal bone cysts, can enlarge faster than most malignancies. Several conditions, such as osteomyelitis, can simulate the appearance of benign bone tumors.

Many benign bone tumors are diagnosed incidentally or after pathologic fracture. Management of these fractures is similar to that of nonpathologic fractures in the same location. It is unusual for benign bone tumors to interfere with fracture healing. Likewise, the fractures rarely result in changes or healing of these tumors, which usually are treated after the fracture has healed.

Radiographs of any suspected bone lesion should always be obtained in 2 planes. Additional studies may be necessary to help arrive at the correct diagnosis and to guide treatment. Although these lesions are benign, many do require intervention.

Osteochondroma (exostosis) is one of the most common benign bone tumors in children. Because many are completely asymptomatic and unrecognized, the true incidence of this lesion is unknown. Most osteochondromas develop in childhood, arising from the metaphysis of a long bone, particularly the distal femur, proximal humerus, and proximal tibia. The lesion enlarges with the child until skeletal maturity. Most are discovered at 5-15 yr of age, when the child or parent notices a bony, nonpainful mass. Some are discovered because they are irritated by pressure during athletic or other activities. Osteochondromas appear radiographically as stalks or broad-based projections from the surface of the bone, usually in a direction away from the adjacent joint. Invariably, the lesion is radiographically smaller than suggested by palpation because the cartilage cap covering the lesion is not seen. This cartilage cap may be up to 1 cm thick. Both the cortex of the bone and the marrow space of the involved bone are continuous with the lesion. Malignant degeneration of a chondrosarcoma is rare in children but occurs in as many as 1% of adults. Routine removal is not performed unless the lesion is large enough to cause symptoms or grows rapidly.

Multiple hereditary exostoses is a related but rare condition characterized by the presence of multiple osteochondromas. Severely involved children can have short stature, limb-length inequality, premature partial physeal arrests, and deformity of both the upper and lower extremities. These children must be monitored carefully during growth.

Enchondroma is a benign lesion of hyaline cartilage that occurs centrally in the bone. Most of these lesions are asymptomatic and occur in the hands. Most are discovered incidentally, although pathologic fractures often lead to the diagnosis. Radiographically, the lesions occupy the medullary canal, are radiolucent, and are sharply marginated. Punctate or stippled calcification may be present within the lesion, but this is much more common in adults than in children. Almost all enchondromas are solitary. Most can simply be observed, with curettage and bone grafting reserved for lesions that are symptomatic or large enough to weaken the bone structurally. Multifocal involvement is referred to as **Ollier disease** and can result in bone dysplasia, short stature, limb-length inequality, and joint deformity. Surgery may be necessary to correct or prevent such deformities. When multiple enchondromas are associated with angiomas of the soft tissue, the condition is referred to as **Maffucci syndrome**. A high rate of malignant transformation has been reported in both of these multifocal conditions.

Chondroblastoma is a rare lesion usually found in the epiphysis of long bones. Most patients present in the 2nd decade with complaints of mild to moderate pain in the adjacent joint. Common sites include the hip, shoulder, and knee. Muscle atrophy and local tenderness may be the only clinical findings. The lesion appears radiographically as a sharply marginated radiolucency within the epiphysis or apophysis, occasionally with metaphyseal extension across the physis. Proximity to the joint can cause deformity of the subchondral bone, an effusion, or erosion into the joint. Recognition is important because most lesions

can be cured with curettage and bone grafting before joint destruction occurs.

Chondromyxoid fibroma is an uncommon benign bone tumor in children. This metaphyseal lesion usually causes pain and local tenderness. The lesion occasionally is asymptomatic. Chondromyxoid fibroma appears radiographically as eccentric, lobular, metaphyseal radiolucency with sharp, sclerotic, and scalloped margins. The lower extremity is involved most often. Treatment usually consists of curettage and bone grafting or en bloc resection.

Osteoid osteoma is a small benign bone tumor. Most of these tumors are diagnosed between 5 and 20 yr of age. The clinical pattern is characteristic, consisting of unremitting and gradually increasing pain that often is worst at night and is relieved by aspirin. Boys are affected more often than girls. Any bone can be involved, but the most common sites are the proximal femur and tibia. Vertebral lesions can cause scoliosis or symptoms that mimic a neurologic disorder. Examination can reveal a limp, atrophy, and weakness when the lower extremity is involved. Palpation and range of motion do not alter the discomfort. Radiographs are distinctive, showing a round or oval metaphyseal or diaphyseal lucency (0.5-1.0 cm in diameter) surrounded by sclerotic bone. The central lucency, or nidus, shows intense uptake on bone scan. Approximately 25% of osteoid osteomas are not visualized on plain radiographs but can be identified with CT. Because of the small size of the lesion and its location adjacent to thick cortical bone, MRI is poor at detecting osteoid osteomas. Treatment is directed at removing the lesion. This can involve en bloc excision, curettage, or percutaneous CT-guided ablation of the nidus. Patients with mild pain may be treated with salicylates. Some lesions resolve spontaneously after skeletal maturity.

Osteoblastoma is a locally destructive, progressively growing lesion of bone with a predilection for the vertebrae, although almost any bone may be involved. Most patients note the insidious onset of dull aching pain, which may be present for months before patients seek medical attention. Spinal lesions can cause neurologic symptoms or deficits. The radiographic appearance is variable and less distinctive than that of other benign bone tumors. Approximately 25% show features suggesting a malignant neoplasm, making biopsy necessary in many cases. Expansile spinal lesions often involve the posterior elements. Treatment involves curettage and bone grafting or en bloc excision; care must be taken to preserve nerve roots when treating spinal lesions. Surgical stabilization of the spine may be necessary.

Fibromas (nonossifying fibroma, fibrous cortical defect, metaphyseal fibrous defect) are fibrous lesions of bone that occur in 40% of children older than 2 yr of age. They most likely represent a defect in ossification rather than a neoplasm and usually are asymptomatic. Most are discovered incidentally when radiographs are taken for other reasons, usually to rule out a fracture after trauma. Occasional pathologic fractures can occur through rare large lesions. Physical examination usually is unrevealing. Radiographs show a sharply marginated eccentric lucency in the metaphyseal cortex. Lesions may be multilocular and expansile, with extension from the cortex into the medullary bone. The long axis of the lesion runs parallel to that of the bone. Approximately 50% are bilateral or multiple. Because of the characteristic radiographic appearance, most lesions do not require biopsy or treatment. Spontaneous regression can be expected after skeletal maturity. Curettage and bone grafting may be recommended for lesions occupying >50% of the bone diameter because of the risk of a pathologic fracture.

Unicameral bone cysts can occur at any age in childhood but are rare in children younger than 3 yr of age and after skeletal maturity. The cause of these fluid-filled lesions is unknown. Some resolve spontaneously after skeletal maturity is reached. Most are asymptomatic until diagnosis, which usually follows a pathologic fracture. Such fractures can occur with relatively minor trauma, such as with throwing or catching a ball. Unicameral bone cysts appear radiographically as solitary, centrally located lesions within the medullary portion of the bone. These cysts are most common in the proximal humerus or femur. They often extend to (but not through) the physis and are sharply marginated. The cortex expands, but that does not exceed the width of the adjacent physis. Treatment involves allowing the pathologic fracture to heal, followed by aspiration and injection with methylprednisolone or bone marrow. Repeat injections, curettage, and bone grafting occasionally are necessary to treat recurrent lesions.

Aneurysmal bone cyst is a reactive lesion of bone seen in persons younger than 20 yr of age. The lesion is characterized by cavernous spaces filled with blood and solid aggregates of tissue. Although the femur, tibia, and spine are most commonly involved, this progressively growing, expansile lesion develops in any bone. Pain and swelling are common. Spinal involvement can lead to cord or nerve root compression and associated neurologic symptoms, including paralysis. Radiographs show eccentric lytic destruction and expansion of the metaphysis surrounded by a thin sclerotic rim of bone. Posterior elements of the spine are involved more commonly than the vertebral body. Unlike most other benign bone tumors, which usually are confined to a single bone, aneurysmal bone cysts can involve adjacent vertebrae. Rapid growth is characteristic and can lead to confusion with malignant neoplasms. Treatment consists of curettage and bone grafting or excision. Spinal lesions can require stabilization after excision. As with other benign tumors, attempts are made to preserve nerve roots and other vital structures. Recurrence after surgical treatment occurs in 20-30% of patients, is more common in younger than older children, and usually occurs in the 1st 1-2 yr after treatment.

Fibrous dysplasia is a developmental abnormality characterized by fibrous replacement of cancellous bone. Lesions may be solitary or multifocal (polyostotic), relatively stable, or progressively more severe. Most children are asymptomatic, although those with skull involvement might have swelling or exophthalmos. Pain and limp are characteristic of proximal femoral involvement. Limb-length discrepancy, bowing of the tibia or femur, and pathologic fractures may be presenting complaints. The triad of polyostotic disease, precocious puberty, and cutaneous pigmentation is known as Albright syndrome. Radiographic features of fibrous dysplasia include a lytic or ground-glass expansile lesion of the metaphysis or diaphysis. The lesion is sharply marginated and often is surrounded by a thick rim of sclerotic bone. Bowing, especially of the proximal femur, may be present. Treatment usually involves observation. Surgery is indicated for patients with progressive deformity, pain, or impending pathologic fractures. Bone grafting is not as successful in the treatment of fibrous dysplasia as with other benign tumors, because the lesion often recurs within the grafted bone. Reconstructive surgical techniques often are necessary to provide stability.

Osteofibrous dysplasia affects children 1-10 yr of age. This lesion usually involves the tibia. It is clinically, radiographically, and histologically distinct from fibrous dysplasia. Most children present with anterior swelling or enlargement of the leg. Progression is unlikely after 10 yr of age. Radiographs show solitary or multiple lucent cortical diaphyseal lesions surrounded by sclerosis. Anterior bowing of the tibia often is present. The radiographic appearance closely resembles that of adamantinoma, a malignant neoplasm, making biopsy more common than with other benign bone tumors. Treatment involves observation. Some lesions heal spontaneously. Excision and bone grafting should be delayed until the child is older than 10 yr of age because of a high recurrence rate before this age. Pathologic fractures heal with immobilization.

Langerhans cell histiocytosis is a monostotic or polyostotic disease that can also involve the skin, liver, or other organs. Single-site disease should be distinguished from the other forms of Langerhans cell histiocytosis (Hand-Schüller-Christian or Letterer-Siwe variants), which can have a less favorable prognosis (see Chapter 507). Langerhans cell histiocytosis usually occurs during the 1st 3 decades of life and is most common in boys 5-10 yr of age. The skull is most commonly affected, but any bone may be involved. Patients usually present with local pain and swelling. Marked tenderness and warmth often are present in the area of the involved bone. Spinal lesions can cause pain, stiffness, and occasional neurologic symptoms. The radiographic appearance of the skeletal lesions is similar in all forms of Langerhans cell histiocytosis but is variable enough to mimic many other benign and malignant lesions of bone. The radiolucent lesions have well-defined or irregular margins with expansion of the involved bone and periosteal new bone formation. Spine involvement can cause uniform compression or flattening of the vertebral body. A skeletal survey is warranted because

polyostotic involvement and the typical skull lesions strongly suggest the diagnosis of eosinophilic granuloma. Biopsy often is necessary to confirm the diagnosis because of the broad radiographic differential diagnosis. Treatment includes curettage and bone grafting, low-dose radiation therapy, or corticosteroid injection. Observation for symptomatic lesions is reasonable because most osseous lesions heal spontaneously and do not recur. Children with bone lesions should be evaluated for visceral involvement because treatment of Hand-Schüller-Christian disease and Letterer-Siwe disease is more complex and often systemic.

Chapter 502

Retinoblastoma

Nidale Tarek and Cynthia E. Herzog

Retinoblastoma is an embryonal malignancy of the retina and the most common intraocular tumor in children. Although the survival rate of children in the United States and developed countries with retinoblastoma is extremely high, retinoblastoma progresses to metastatic disease and death in over 50% of children worldwide. Furthermore, the associated loss of vision and side effects of therapy are significant problems that remain to be addressed.

EPIDEMIOLOGY

Approximately 250-350 new cases of retinoblastoma are diagnosed each year in the United States, with no known racial or gender predilection. The cumulative lifetime incidence of retinoblastoma is approximately 1 : 20,000 live births, and retinoblastoma accounts for 4% of all pediatric malignancies. The median age at diagnosis is approximately 2 yr, and more than 90% of cases are diagnosed in children younger than 5 yr of age. Overall, about 66-75% of children with retinoblastoma have unilateral tumors, with the remainder having bilateral retinoblastoma. Bilateral involvement is more common in younger children, particularly in those diagnosed younger than the age of 1 yr, and is always heritable. There is a possible increased risk of retinoblastoma in children conceived by in vitro fertilization.

Retinoblastoma can be either hereditary or sporadic. Hereditary cases usually are diagnosed at a younger age and are multifocal and bilateral, whereas sporadic cases are usually diagnosed in older children who tend to have unilateral, unifocal involvement. The hereditary form is associated with loss of function of the **retinoblastoma gene *(RB1)*** via gene mutation or deletion. The *RB1* gene is located on chromosome 13q14 and encodes the **retinoblastoma protein,** a tumor-suppressor protein that controls cell-cycle phase transition and has roles in apoptosis and cell differentiation. Many different causative mutations have been identified, including translocations, deletions, insertions, point mutations, and epigenetic modifications such as gene methylation. The nature of the predisposing mutation can affect the penetrance and expressivity of retinoblastoma development.

According to Knudson's "two-hit" model of oncogenesis, 2 mutational events are required for retinoblastoma tumor development (see Chapter 492). In the hereditary form of retinoblastoma, the first mutation in the *RB1* gene is inherited through germinal cells and a second mutation occurs subsequently in somatic retinal cells. Second mutations that lead to retinoblastoma often result in the loss of the normal allele and concomitant loss of heterozygosity. Parents and siblings of a child with a germline mutation should be referred to a genetic specialist for testing; most children with hereditary retinoblastoma have spontaneous new germinal mutations, and both parents have wild-type retinoblastoma genes. All 1st-degree relatives of children with known or suspected hereditary retinoblastoma should have retinal examinations to identify retinomas or retinal scars, which may suggest hereditary retinoblastoma even though malignant retinoblastoma did not develop. In the sporadic form of retinoblastoma, the 2 mutations occur in somatic retinal cells. Heterozygous carriers of oncogenic *RB1* mutations demonstrate variable phenotypic expression.

PATHOGENESIS

Histologically, retinoblastoma appears as a small round blue cell tumor with rosette formation (Flexner-Wintersteiner rosettes). It may arise in any of the nucleated layers of the retina and exhibit various degrees of differentiation. Retinoblastoma tumors tend to outgrow their blood supply, resulting in necrosis and calcification.

Endophytic tumors arise from the inner surface of the retina and grow into the vitreous, and can also grow as tumors suspended within the vitreous itself, known as **vitreous seeding.** Exophytic tumors grow from the outer retinal layer and can cause retinal detachment. Diffuse infiltrating tumors grow intraretinally and remain flat; these are less common and can cause iris neovascularization. Tumors can also be both endophytic and exophytic. These tumors can also spread by direct extension to the choroid or along the optic nerve beyond the lamina cribrosa to the central nervous system, or by hematogenous or lymphatic spread to distant sites, including bones, bone marrow, and lungs.

CLINICAL MANIFESTATIONS

Retinoblastoma classically presents with **leukocoria,** a white pupillary reflex (Fig. 502-1), which often is first noticed when a red reflex is not present at a routine newborn or well-child examination or in a flash photograph of the child. Strabismus often is an initial presenting complaint. Decreased vision, orbital inflammation, hyphema, and pupil irregularity can occur with advancing disease. Pain can occur if secondary glaucoma is present. Only approximately 10% of retinoblastoma cases are detected by routine ophthalmologic screening in the context of a positive family history.

DIAGNOSIS

The diagnosis is established by the characteristic ophthalmologic findings of a chalky, white-gray retinal mass with a soft, friable consistency.

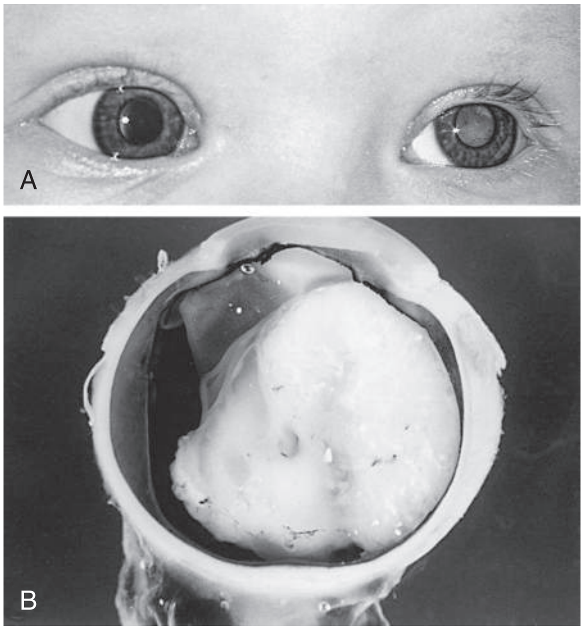

Figure 502-1 A, Leukocoria noted in the left eye of a child presenting with retinoblastoma. **B,** A large white tumor mass noted within the posterior chamber of the enucleated eye. *(From Shields JA, Shields CL: Current management of retinoblastoma,* Mayo Clin Proc *69:50–56, 1994.)*

Imaging studies are not diagnostic, and biopsies are contraindicated. Indirect ophthalmoscopy with slit-lamp evaluation can detect retinoblastoma tumors, but a complete evaluation requires an examination under general anesthesia by an experienced ophthalmologist to obtain complete visualization of both eyes, which also facilitates photographing and mapping of the tumors. Retinal detachment or vitreous hemorrhage can complicate the evaluation.

Orbital ultrasonography, CT, or MRI is used to evaluate the extent of intraocular disease and extraocular spread. Occasionally (~60%), a pineal area (primitive neuroectodermal) tumor is detected in a child with hereditary and bilateral retinoblastoma, a phenomenon known as **trilateral retinoblastoma.** MRI allows for better evaluation of optic nerve involvement. Metastatic disease is rarely present at diagnosis; evaluation of the cerebrospinal fluid and bone marrow for tumor metastasis and radionuclide bone scan are required only if indicated by other clinical, laboratory, or imaging findings.

The **differential diagnosis** of retinoblastoma includes other causes of leukocoria, including persistent hyperplastic primary vitreous, Coats disease, vitreous hemorrhage, cataract, endophthalmitis from *Toxocara canis*, choroidal coloboma, retinopathy of prematurity, and familial exudative vitreoretinopathy.

TREATMENT

Treatment is determined by the size and location of the tumors, if the disease is localized to the eye or has spread either to the brain or to the rest of the body, and whether the child has hereditary or sporadic disease. The primary goal of treatment is always cure; the secondary goals include preserving vision and the eye itself and decreasing the risk of late side effects, mainly secondary malignancies. As newer modalities for local control of intraocular tumors and more effective systemic chemotherapy have emerged, primary enucleation is being performed less often.

Most unilateral disease presents with a solitary, large tumor. Enucleation is performed if there is no potential for the salvage of useful vision. With bilateral disease, chemoreduction in combination with **focal therapy** (laser photocoagulation or cryotherapy) has replaced the traditional approach of enucleation of the more severely affected eye and irradiation of the remaining eye. If feasible, small tumors can be treated with focal therapy with careful follow-up for recurrence or new tumor growth. Larger tumors often respond to multiagent chemotherapy, including carboplatin, vincristine, and etoposide. If this approach fails, external-beam irradiation should be considered, although this approach may result in significant orbital deformity and increased incidence of second malignancies in patients with germline *RB1* mutations. Brachytherapy, or episcleral plaque radiotherapy, is an alternative with less morbidity. Enucleation may be required for unresponsive or recurrent tumors. Alternative treatment options currently under investigation include other systemic chemotherapy agents such as topotecan, other methods of chemotherapy administration, including periocular, intravitreal, and ophthalmic artery infusions, and intense multiagent chemotherapy with autologous stem cell rescue for patients with metastatic disease.

PROGNOSIS

Approximately 95% of children in the United States with retinoblastoma are cured with modern treatment. Current efforts using chemotherapy in combination with focal therapy are intended to preserve useful vision and avoid external-beam radiation or enucleation. Routine ophthalmologic examinations should continue until children are older than age 7 yr. Unfortunately, the diagnosis of retinoblastoma in many children from 3rd-world countries is delayed, resulting in spread of the tumor outside of the orbit. The prognosis for children with retinoblastoma that has spread outside of the eye is poor. Trilateral retinoblastoma, disease involving both eyes and the pineal region, is almost universally fatal.

Children with germline *RB1* mutations are at significant risk for development of second malignancies, especially osteosarcoma and also soft tissue sarcomas and malignant melanoma. The risk of second malignancies is further increased by the use of radiation therapy. Other radiation-related late adverse effects include cataracts, orbital growth deformities, lacrimal dysfunction, and late retinal vascular injury.

Chapter 503

Gonadal and Germ Cell Neoplasms

Cynthia E. Herzog and Winston W. Huh

EPIDEMIOLOGY

Malignant germ cell tumors (GCTs) and gonadal tumors are rare, with an incidence of 12 cases per 1 million persons younger than 20 yr of age. Most malignant tumors of the gonads in children are GCTs. The incidence varies according to age and sex, although the incidence of GCTs in adolescent males has increased over time. Sacrococcygeal tumors occur predominantly in infant girls. Testicular GCTs occur predominantly before age 4 yr and after puberty. Klinefelter syndrome is associated with an increased risk of mediastinal GCTs; Down syndrome, undescended testes, infertility, testicular atrophy, testicular microlithiasis, testicular dysgenesis syndrome, and inguinal hernias are associated with an increased risk of testicular cancer. The risk of testicular cancer in patients with cryptorchidism is reduced but not eliminated if orchiopexy is performed before 13 yr of age. The risk of testicular GCT is increased in 1st-degree relatives and is highest among monozygotic twins.

PATHOGENESIS

The GCTs and non-GCTs arise from primordial germ cells and coelomic epithelium, respectively. Testicular and sacrococcygeal GCTs arising during early childhood characteristically have deletions at chromosome arms 1p and 6q and gains at 1q, and lack the isochromosome 12p that is highly characteristic of malignant GCTs of adults. Testicular GCT also may demonstrate loss of imprinting. Ovarian GCTs from older girls characteristically have deletions at 1p and gains at 1q and 21. Because GCTs may contain benign and mixed malignant elements in different areas of the tumor, extensive sectioning is essential to confirm the correct diagnosis. The many histologically distinct subtypes of GCTs include teratoma (mature and immature), endodermal sinus tumor, and embryonal carcinoma (Fig. 503-1). Non-GCTs of the ovary include epithelial (serous and mucinous) and sex cord–stromal tumors; non-GCTs of the testicle include sex cord/stromal (e.g., Leydig cell, Sertoli cell) tumors. *DICER1* mutations have been observed in nonepithelial ovarian cancers, especially in Sertoli-Leydig tumors.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of germ cell neoplasms depends on location. Ovarian tumors often are quite large by the time they are diagnosed (Fig. 503-2). Extragonadal GCTs occur in the midline, including the suprasellar region, pineal region, neck, mediastinum, and retroperitoneal and sacrococcygeal areas (Fig. 503-3). Symptoms relate to mass effect, but the intracranial GCTs often present with anterior and posterior pituitary deficits (see Chapter 497).

The **serum α-fetoprotein (AFP)** level is elevated with endodermal sinus tumors and may be minimally elevated with teratomas. Infants normally have higher levels of AFP, which fall to normal adult levels by about age 8 mo; consequently, high AFP levels must be interpreted with caution in this age group. Elevation of the β subunit of **human chorionic gonadotropin,** which is secreted by syncytiotrophoblasts, is seen with choriocarcinoma and germinomas. Lactate dehydrogenase,

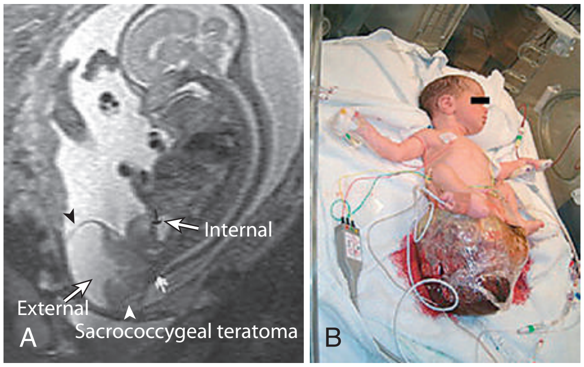

Figure 503-3 **A,** Prenatal MRI showing sacrococcygeal teratoma with a small internal and large external component. **B,** Postnatal large bleeding sacrococcygeal teratoma. *(From Lakhoo K. Neonatal teratomas.* Early Hum Dev *86(10):643–647, 2010.)*

although nonspecific, may be a useful marker. If elevated, these markers provide important confirmation of the diagnosis and provide a means to monitor the patient for tumor response and recurrence. Both serum and cerebrospinal fluid should be assayed for these markers in patients with intracranial lesions.

Diagnosis begins with physical examination and imaging studies, including plain radiographs of the chest and ultrasonography of the abdomen. CT or MRI can further delineate the primary tumor. If germ cell malignancy is strongly suggested, preoperative staging with CT of the chest and bone scan is appropriate. Primary surgical resection is indicated for tumors deemed resectable. For older patients with testicular tumors, ipsilateral retroperitoneal lymph node sampling may be required to determine extent of disease and aid in treatment planning. Ovarian tumors also require detailed surgical evaluation including lymph node removal and pelvic washings for cytologic analysis for peritoneal spread. Diagnosis of intracranial lesions can be established with imaging and AFP or β-human chorionic gonadotropin determinations of serum and cerebrospinal fluid.

Gonadoblastomas often occur in patients with gonadal dysgenesis and all or parts of a Y chromosome. Gonadal dysgenesis is characterized by failure to fully masculinize the external genitalia. If this syndrome is diagnosed, imaging of the gonad with ultrasonography or CT is performed, and surgical resection of the tumor usually is curative. Prophylactic resection of dysgenetic gonads at the time of diagnosis is recommended, because gonadoblastomas, some of which contain malignant GCT elements, often develop. Gonadoblastomas may produce abnormal amounts of estrogen.

Teratomas occur in many locations, presenting as masses. They are not associated with elevated markers unless malignancy is present. The sacrococcygeal region is the most common site for teratomas. Sacrococcygeal teratomas occur most commonly in infants and may be diagnosed in utero or at birth, with most found in girls. The rate of malignancy in this location varies, ranging from <10% in children younger than 2 mo of age to >50% in children older than 4 mo of age.

Germinomas occur intracranially, in the mediastinum, and in the gonads. In the ovary, they are called **dysgerminomas;** in the testis,

seminomas. They usually are tumor-marker–negative masses despite being malignant. Endodermal sinus or yolk sac tumor and choriocarcinoma appear highly malignant by histologic criteria. Both occur at gonadal and extragonadal sites. Embryonal carcinoma most often occurs in the testes. Choriocarcinoma and embryonal carcinoma rarely occur in the pure form and are usually found as part of a mixed malignant GCT.

Non–germ cell gonadal tumors are very uncommon in pediatrics and occur predominantly in the ovary. Epithelial carcinomas (usually an adult tumor), Sertoli-Leydig cell tumors, and granulosa cell tumors may occur in children. Carcinomas account for about one third of ovarian tumors in females younger than 20 yr of age; most of these occur in older teens and are of the serous or mucinous subtype. Sertoli-Leydig cell tumors and granulosa cell tumors produce hormones that can cause virilization, feminization, or precocious puberty, depending on pubertal stage and the balance between Sertoli cells (estrogen production) and Leydig cells (androgen production). Diagnostic evaluation usually focuses on the chief complaint of inappropriate sex steroid effect and includes hormone measurements, which reflect gonadotropin-independent sex steroid production. Appropriate imaging also is performed to rule out a functioning gonadal tumor. Surgery usually is curative. No effective therapy for nonresectable disease has been found.

TREATMENT

Complete surgical excision of the tumor usually is indicated, except for patients with intracranial tumors, where the primary therapy consists of radiation therapy and chemotherapy. For testicular tumors, an inguinal approach is indicated, and complete resection should include the entire spermatic cord. When complete excision cannot be accomplished, preoperative chemotherapy is indicated, with second-look surgery. For completely resected nonseminomatous testicular tumors, there is debate on whether patients can be clinically observed following surgery. For teratomas, both mature and immature, and completely resected malignant tumors of the testes, surgery alone is the treatment. For ovarian tumors, unless the contralateral ovary is obviously also involved by tumor, a fertility-sparing surgery should be performed. Cisplatin-based chemotherapy regimens usually are curative in GCTs that cannot be completely resected, even if metastases are present. However, sex cord–stromal tumors tend to be refractory to chemotherapy. Except for GCTs of the central nervous system, radiation therapy is limited to those tumors that are not amenable to complete excision and are refractory to chemotherapy.

PROGNOSIS

The overall cure rate for children with GCTs is >80%. Age is the most predictive factor of survival for extragonadal GCTs. Children older than 12 yr of age have a 4-fold higher risk of death, and a 6-fold higher risk if the tumor is thoracic. Histology has little effect on prognosis. Nonresected extragonadal GCTs have a slightly worse prognosis.

Chapter 504
Neoplasms of the Liver
Nidale Tarek and Cynthia E. Herzog

Hepatic tumors are rare in children. Primary tumors of the liver account for approximately 1% of malignancies in children younger than 15 yr of age, with an annual incidence of 1.6 cases per 1 million children in the United States. Between 50% and 60% of hepatic tumors in children are malignant, with >65% of these malignancies being hepatoblastomas and most of the remainder being hepatocellular carcinomas. Rare hepatic malignancies include embryonal sarcoma, angiosarcoma, malignant germ cell tumor, rhabdomyosarcoma of the liver, and undifferentiated sarcoma. More common childhood malignancies, such as neuroblastoma, Wilms tumor, and lymphoma, can metastasize to the liver. Benign liver tumors, which usually present in the 1st 6 mo of life, include hemangiomas, hamartomas, and hemangioendotheliomas.

HEPATOBLASTOMA
Epidemiology
Approximately 100 new cases of hepatoblastoma are diagnosed each yr in the United States. Hepatoblastoma occurs predominantly in children younger than 3 yr of age and the median age of diagnosis is 1 yr. The etiology is unknown. Hepatoblastomas are associated with familial adenomatous polyposis. Alterations in the antigen-presenting cell/β-catenin pathway have been found in most of the tumors evaluated. Hepatoblastomas are also associated with Beckwith-Wiedemann syndrome, hemihyperplasia, and other somatic overgrowth syndromes. Increased expression of insulin-like growth factor 2 secondary to genetic mutations or epigenetic changes is implicated in hepatoblastoma development in patients with Beckwith-Wiedemann syndrome. All children with Beckwith-Wiedemann syndrome or hemihyperplasia should be routinely screened with α-fetoprotein (AFP) levels and abdominal ultrasounds. Prematurity and low birthweight is associated with increased incidence of hepatoblastoma, with the risk increasing as birthweight decreases.

Pathogenesis
Hepatoblastoma arises from precursors of hepatocytes and is histologically classified as whole epithelial type, containing fetal or embryonal malignant cells (either as a mixture or as pure elements), and mixed type, containing both epithelial and mesenchymal elements. Histologic classification has a direct correlation with clinical outcome. The pure fetal histology subtype predicts a more favorable outcome and the small cell undifferentiated subtype is associated with normal AFP levels and predicts a worse outcome.

Clinical Manifestations
Hepatoblastoma usually presents as a large, asymptomatic abdominal mass. It arises from the right lobe 3 times more often than the left and usually is unifocal. As the disease progresses, fatigue, fever, weight loss, anorexia, vomiting, and abdominal pain may ensue. Rarely, hepatoblastoma presents with hemorrhage secondary to trauma or spontaneous rupture. Metastatic spread of hepatoblastoma most commonly involves regional lymph nodes and the lungs.

Diagnosis
A biopsy of liver tumors is necessary to establish the diagnosis. A valuable serum tumor marker, **AFP,** is used in the diagnosis and monitoring of hepatic tumors. The AFP levels are elevated in almost all hepatoblastomas. Bilirubin and liver enzymes usually are normal. Anemia is common, and thrombocytosis occurs in approximately 30% of patients. Serologic testing for hepatitides B and C should be performed, but the results usually are negative in hepatoblastoma.

Diagnostic imaging should include plain radiographs and ultrasonography of the abdomen to characterize the hepatic mass. Ultrasonography can differentiate malignant hepatic masses from benign vascular lesions. Either CT or MRI is an accurate method of defining the extent of intrahepatic tumor involvement and the potential for surgical resection. Evaluation for metastatic disease should include CT of the chest.

Treatment
In general, the cure of malignant hepatic tumors in children depends on complete resection of the primary tumor (Fig. 504-1); as much as 85% of the liver can be resected, with hepatic regeneration noted within 3-4 mo after surgery. Treatment of hepatoblastoma is based on surgery and systemic chemotherapy using cisplatin in combination with vincristine and 5-fluorouracil or doxorubicin. In 30% of cases,

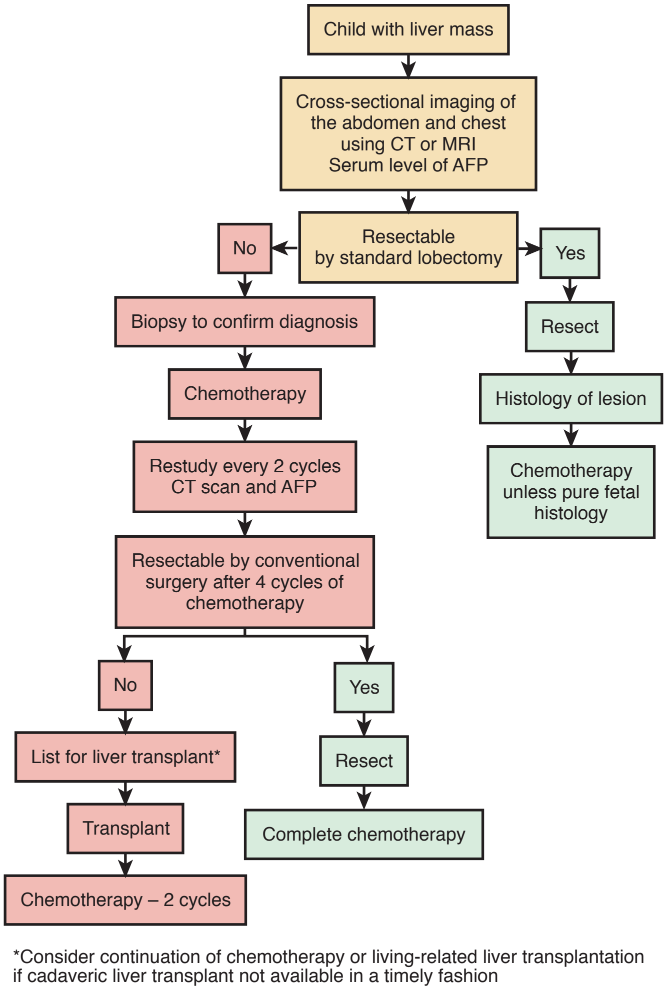

Figure 504-1 Algorithm for the management of a child who presents with a hepatoblastoma. *AFP*, α-fetoprotein. *(From Tiao GM, Bobey N, Allen S, et al: The current management of hepatoblastoma: a combination of chemotherapy, conventional resection, and liver transplantation,* J Pediatr *146:204–211, 2005.)*

tumors are resectable at diagnosis; a safe attempt for initial gross total resection should be made followed by adjuvant chemotherapy. Unresectable tumors with or without metastatic disease, at presentation, usually respond to chemotherapy; preresection chemotherapy is indicated, and excision of the primary tumor and extrahepatic disease should be attempted as soon as it becomes feasible, followed by additional chemotherapy. Liver transplant is a viable option for unresectable primary hepatic malignancies and results in good long-term survival. The pretransplant medical condition is an important predictor of outcome, and thus transplant is much more effective as the primary surgery than as salvage therapy. Alternative treatment options currently under investigation include other systemic chemotherapy agents such as carboplatin, ifosfamide, etoposide, and irinotecan. Other treatment approaches include transarterial chemoembolization, cryoablation, and radiofrequency ablation.

Prognosis

In low-stage tumors, survival rates >90% can be achieved with multimodal treatment, including surgery and adjuvant chemotherapy. With tumors unresectable at diagnosis, survival rates of approximately 60% can be obtained. Metastatic disease further reduces survival, but complete regression of disease often can be obtained with chemotherapy and surgical resection of the primary tumor and isolated pulmonary metastatic disease, resulting in survival rates of approximately 25%. Treatment-related long-term adverse effects include cardiac toxicity with doxorubicin and renal and ototoxicity with cisplatin.

HEPATOCELLULAR CARCINOMA

Epidemiology

Hepatocellular carcinoma occurs mostly in adolescents and often is associated with hepatitis B or C infection. It is more common in East Asia and other areas where hepatitis B is endemic; the incidence has decreased following the introduction of hepatitis B vaccination. In these areas it also tends to occur in a bimodal pattern, with the younger age peak overlapping the age of hepatoblastoma presentation. It also occurs in the chronic form of hereditary tyrosinemia, galactosemia, glycogen storage disease, α_1-antitrypsin deficiency, and biliary cirrhosis. Aflatoxin B contamination of food is another risk factor.

Pathogenesis

Hepatocellular carcinoma usually arises in an abnormal or cirrhotic liver and presents as a multicentric, invasive tumor consisting of large pleomorphic cells of epithelial origin. Compared to adults, cirrhosis in children is less common and congenital liver disorders are more common. Hepatocellular carcinomas are classified as classical or fibrolamellar. The fibrolamellar variant occurs more often in adolescent and young adult patients and is not associated with cirrhosis. Although previous reports have suggested that the fibrolamellar type has a better prognosis, more recent data analysis refutes this.

Clinical Manifestations

Hepatocellular carcinoma usually presents as a hepatic mass with abdominal distention and symptoms of anorexia, weight loss, and abdominal pain. Hepatocellular carcinoma can present as an acute abdominal crisis with rupture of the tumor and hemoperitoneum. Metastatic spread usually involves regional lymph nodes and the lungs. The AFP level is elevated in approximately 60% of children. Evidence of hepatitides B and C infection usually is found in endemic areas but not in Western countries or with the fibrolamellar type. Bilirubin usually is normal, but liver enzymes may be abnormal.

Diagnostic imaging should include plain radiographs and ultrasonography of the abdomen to characterize the hepatic mass. Ultrasonography can differentiate malignant hepatic masses from benign vascular lesions. Either CT or MRI is an accurate method of defining the extent of intrahepatic tumor involvement and the potential for surgical resection. Evaluation for metastatic disease should include CT of the chest.

Treatment

Complete tumor resection is crucial for curative treatment. Because of the multicentric origin of hepatocellular carcinoma and underlying liver disease, complete resection is accomplished in only 30-40% of cases. A gross total resection should be attempted at diagnosis when possible; combination chemotherapy following surgery is necessary. For unresectable tumors, chemotherapy followed by surgical assessment is essential; liver transplant is an option for unresectable tumors. Even with complete surgical resection, only 30% of children are long-term survivors. Chemotherapy, including cisplatin, doxorubicin, etoposide, and 5-fluorouracil, has shown some activity against this tumor, but improved long-term outcome has been difficult to achieve. Other techniques, such as cryosurgery, radiofrequency ablation, transarterial chemoembolization, and ethanol injection, are under study as therapy for hepatocellular carcinomas.

Chapter 505
Benign Vascular Tumors

505.1 Hemangiomas

Cynthia E. Herzog

Hemangiomas, the most common benign tumors of infancy, occur in approximately 5-10% of term infants (see Chapter 650). The risk of hemangioma is 3-5 times higher in girls than boys. The risk is doubled in premature infants and 10 times higher in offspring of women who had chorionic villus sampling. Hemangiomas can be present at birth but usually arise shortly after birth and grow rapidly during the 1st yr of life, with slowing of growth in the next 5 yr and involution by 10-15 yr of age.

CLINICAL MANIFESTATIONS

More than 50% of all hemangiomas are located in the head and neck region. Most are solitary lesions, but the presence of more than 1 cutaneous lesion increases the likelihood of visceral hemangiomas. The liver is the primary site of visceral involvement; other involved organs include the brain, intestines, and lung. Infantile hemangiomas can be differentiated from other lesions with which they may be confused by the expression of GLUT1. Most hemangiomas require no therapy, but approximately 10% of hemangiomas cause significant impairment and 1% are life-threatening because of their location. Hemangiomas around the airway can cause airway obstruction, and those around the eyes can result in loss of vision. Ulceration is a common complication and can lead to secondary infection. With or without treatment, after involution of a hemangioma, residual skin abnormalities remain. Large hepatic hemangiomas or hemangioendotheliomas may result in hepatomegaly, anemia, thrombocytopenia, and high-output heart failure.

Kasabach-Merritt syndrome (see Chapter 650) is characterized by a rapidly enlarging lesion, thrombocytopenia, microangiopathic hemolytic anemia, and coagulopathy as a result of platelet and red blood cell trapping and activation of the clotting system within the vasculature of the hemangioma. This syndrome is associated with kaposiform hemangioendotheliomas or tufted angiomas but not with infantile hemangiomas.

Cutaneous lesions usually can be diagnosed by typical appearance and rapid proliferation. Segmental hemangiomas, or those with geographic localization and some plaque-like features, recently have been shown to have a higher risk of complications and association with developmental abnormalities. A deep lesion may require imaging studies to help differentiate it from a lymphangioma. The presence of a midline hemangioma in the lumbosacral area indicates the need for an MRI to search for underlying asymptomatic neurologic abnormalities. Location also may dictate the need for an ophthalmologic or surgical consultation. An ultrasonographic scan or MRI of the liver should be performed if multiple cutaneous lesions are present.

TREATMENT

See Chapter 650.

Bibliography is available at Expert Consult.

505.2 Lymphangiomas and Cystic Hygromas

Cynthia E. Herzog

Lymphatic malformations, including lymphangiomas and cystic hygromas, which arise in the embryonic lymph sac, are the second most common benign vascular tumors in children. About half are located in the head and neck area. Approximately 50% are present at birth, with most presenting by 2 yr of age. There is no gender predisposition. Spontaneous regression has been reported but is not typical.

Lymphatic malformations present as soft, painless masses that transilluminate if superficial. Intrathoracic lymphatic malformation can present as symptoms related to a mediastinal mass or pericardial or pleural effusion. Rapid enlargement can occur with infection or hemorrhage. Localized lesions may be surgically resected, but this can be difficult, owing to their infiltrative nature. Recurrence is common with incompletely resected lesions. Aspiration can provide temporary relief in an emergency, such as in the presence of dyspnea, but reaccumulation will occur. Treatment by injection of sclerosing agents, laser therapy, and systemic interferon therapy also has been used. The streptococcal immunotherapeutic agent OK-432 (Picibanil) is the sclerosing agent of choice; its use will prevent the need for surgery in most cases. Bleomycin is also an effective sclerosing agent but has a risk of pulmonary toxicity. It appears to be especially effective for the treatment of macrocystic lymphangiomas of the head and neck.

Chapter 506
Rare Tumors

506.1 Thyroid Tumors

Steven G. Waguespack

See Chapter 569.

BENIGN THYROID TUMORS

Benign thyroid tumors represent approximately 75% of all thyroid nodules presenting in the pediatric population. The work-up of a suspected thyroid nodule includes the laboratory assessment of thyroid function, ultrasound to assess the nodule and regional lymph node characteristics, and fine-needle aspiration biopsy under ultrasound guidance for definitive pathologic diagnosis. Nuclear scintigraphy using radioactive iodine (^{123}I) or ^{99m}Tc-pertechnetate is not recommended in the initial diagnostic evaluation, except in the event of a suppressed thyroid-stimulating hormone (TSH) level.

MALIGNANT THYROID TUMORS

Pediatric thyroid malignancies are rare tumors that include medullary thyroid carcinoma (MTC) and the differentiated thyroid carcinomas (DTCs): papillary thyroid carcinoma (PTC) and follicular thyroid carcinoma. PTC represents the vast majority of thyroid cancers in children, who have an excellent overall prognosis with anticipated survival over decades, even in the presence of metastatic disease at diagnosis. The major established environmental risk factor for the development of PTC is exposure to ionizing radiation.

MTC is a very uncommon disease in childhood that almost always occurs in the context of an autosomal dominant, hereditary endocrine tumor syndrome that arises secondary to activating mutations in the *RET* (*RE*arranged during *T*ransfection) protooncogene: multiple endocrine neoplasia type 2a (MEN2A) or type 2b (MEN2B). In addition to the almost complete penetrance of MTC in the most common *RET* mutations, patients with MEN2A and MEN2B have up to a 50% lifetime risk of developing pheochromocytomas. Up to 20% of MEN2A patients will develop primary hyperparathyroidism. Patients with MEN2B do not develop hyperparathyroidism but have a distinct phenotype with a characteristic facial appearance, marfanoid body habitus, and a generalized ganglioneuromatosis, manifested most obviously by the presence of oral mucosal neuromas (Fig. 506-1). The

Figure 506-1 Classic appearance of oral mucosal neuromas on the tongue in a boy with MEN2B secondary to the typical M918T mutation in the *RET* protooncogene.

pathognomonic phenotype of MEN2B is not apparent in very early childhood, although an inability to cry tears and constipation represent early clues to diagnosis in these patients.

Children with thyroid cancer usually present with an asymptomatic thyroid mass and/or cervical lymphadenopathy, although children with MEN2 are often diagnosed only after a positive genetic test result or, in the case of MEN2B, after the clinical phenotype is recognized. Lymph node metastases are present in the majority of PTC cases and lung metastases are identified in up to 20% of patients, primarily in those children with a high burden of neck disease.

The primary therapy for thyroid cancer is a total thyroidectomy and a compartment-oriented lymph node dissection, as indicated, performed by a highly experienced thyroid cancer surgeon. In DTC, ^{131}I is used postoperatively to treat distant metastasis and unresectable residual neck disease. In PTC, the routine use of ^{131}I is limited to those children who are most likely to benefit from treatment. Children with MTC do not require ^{131}I therapy. The TSH level is initially suppressed by giving supraphysiologic levothyroxine in the case of DTC, as TSH stimulates DTC tumor growth; the TSH is kept normal in the case of MTC. Long-term follow-up involves monitoring of tumor markers (thyroglobulin in DTC and calcitonin/carcinogenic embryonic antigen in MTC), as well as routine imaging, primarily neck ultrasound.

In MEN2, there are well-documented genotype-phenotype correlations, and the biologic aggressiveness of MTC depends on the hereditary setting in which it develops. With the advent of genetic testing for *RET* mutations, MTC has become one of the few malignancies that can be cured via early thyroidectomy before the cancer becomes metastatic. Recommendations regarding the age at surgery of children who are carriers of a *RET* mutation are evolving and incorporate clinical testing (ultrasound and calcitonin levels) in addition to knowledge regarding the genotype. Novel oral tyrosine kinase inhibitors are approved by the FDA for the treatment of advanced MTC and DTC in adults.

506.2 Melanoma

Dennis P.M. Hughes and Cynthia E. Herzog

See Chapter 651.

The incidence of melanoma in persons younger than 20 yr of age in the United States is 4.2 cases per 1 million, with 73% occurring in 15-19 year olds, 17% in 10-14 year olds, and 10% occurring in children younger than 10 yr of age (see Chapter 651). Melanoma is more common among adolescent females than males. In the United States, incident rates of melanoma in younger age groups are increasing, although at a slower rate than in adults. UV light, especially sun exposure, is a well-known risk factor for melanoma in adults, and also contributes to teenage melanoma, as shown by the tendency of lesions to develop on sun-exposed areas in this age group. In younger patients, melanoma does not appear to be associated with sun exposure and often occurs in skin that is not frequently exposed to the sun. Pediatricians should counsel patients regarding avoidance of sun exposure and the use of tanning beds to decrease the risk of later development of melanoma. Patients with fair skin and a family history of melanoma are at particularly high risk. Known risk factors for children are a giant hairy nevus (>10 cm), dysplastic nevus syndrome, and xeroderma pigmentosum. These conditions merit total skin examination at least annually.

Findings of a rapidly enlarging nevus that is dark, has changed colors, has irregular borders, or bleeds easily should raise a concern of melanoma. However, more than half of pediatric melanomas are nonpigmented, and can easily be confused with a wart or other benign finding. Diagnosis is based on pathology, and a punch biopsy is preferred. However, extra care must be taken in the diagnosis of melanoma in children because making the distinction from other lesions, particularly Spitz nevus, can be difficult. Management in a center with expertise in pediatric melanoma may be advisable, especially for anything other than thin melanomas (Breslow thickness of 1 mm or greater).

Prognosis and treatment recommendations have previously been extrapolated from adult data; however, specific prognostic factors for pediatric melanoma are starting to accrue. The initial diagnosis is best made with a punch biopsy. Shave biopsy is specifically discouraged, as this method tends to leave the base of the lesion behind, and specific information about the depth of invasion is lost. Biopsy sites that test positive for melanoma should be reexcised with appropriate margins based on thickness. Lymph node mapping and sentinel node biopsy should also be performed for all melanomas with a Breslow thickness >0.5-1 mm, or any lesions in which the tumor base was not resected. If the sentinel node is positive, a formal lymph node dissection is essential for ensuring the best probability of survival. To date, the treatment of childhood melanoma still mirrors treatment of adult melanoma. High-dose adjuvant interferon shows some efficacy in the treatment of adult melanoma, whereas chemotherapy in combination with biologic agents and vaccine therapy has been used for treatment of distant metastases. Although novel therapies such as targeted B-Raf inhibitors and immune-modulating agents have received regulatory approval for treatment of adult melanoma, their use in children is still investigational.

506.3 Nasopharyngeal Carcinoma

Cynthia E. Herzog

Nasopharyngeal carcinoma is rare in the pediatric population but is one of the most common nasopharyngeal tumors in pediatric patients. In adults, the incidence is highest in South China, but it is also high among the Inuit people and in North Africa and Northeast India. In China, it is rare in the pediatric population, but in other populations a substantial proportion of cases occur in the pediatric age group, primarily in adolescents. It occurs in males twice as often as in females and is more common in blacks. In the pediatric population the tumors are more commonly of undifferentiated histology and associated with Epstein-Barr virus. Nasopharyngeal carcinoma is associated with specific human leukocyte antigen types, and other genetic factors may play a role, especially in low-incidence populations.

Most pediatric patients present with advanced locoregional disease manifesting as cervical lymphadenopathy. Epistaxis, trismus, and cranial nerve deficits also may be present. The diagnosis is established from biopsy of the nasopharynx or cervical lymph nodes. In most cases the lactate dehydrogenase level is elevated, but this finding is nonspecific. CT or MRI evaluation of the head and neck is performed to

determine the extent of locoregional disease. Chest radiography, CT, bone scan, and liver scan are used to evaluate for metastatic disease. Positron emission tomography scans appear to be useful for monitoring both primary disease and looking for metastases. Epstein-Barr virus DNA levels correlate with disease stage, have prognostic value, and can be used to monitor for recurrence.

Treatment is a combination of chemotherapy and irradiation. Cisplatin given concurrently with radiation, with or without neoadjuvant cisplatin-based chemotherapy, is the standard treatment. The outcome depends on the extent of disease; patients with distant metastases have a very poor prognosis. Using intensity-modulated radiation therapy improves local control and reduces the late adverse effects associated with radiation therapy, including hormonal dysfunction, dental caries, fibrosis, and second malignancies. Use of proton therapy may result in further reduction of adverse effects.

506.4 Adenocarcinoma of the Colon and Rectum

Cynthia E. Herzog and Winston W. Huh

Colorectal carcinoma (CRC) is rare in the pediatric population with an estimated incidence rate of approximately 1 case per 1 million. Even in patients with predisposing conditions, CRC usually does not present until late adolescence or adulthood. Hereditary nonpolyposis colon cancer (HNPCC) is an autosomal dominant disorder, with germline mutations in DNA mismatch repair genes *(MMR)* causing DNA repair errors and microsatellite instability. Familial adenomatous polyposis (FAP) and attenuated FAP are autosomal disorders, with germline mutations in the *APC* gene. In addition to CRC, patients with HNPCC, FAP, and attenuated FAP are predisposed to a number of extracolonic cancers. Desmoid tumors can occur in patients with FAP, whereas patients with HNPCC have an increased risk for tumors involving the genitourinary tract, stomach, and small intestine. *MYH*-associated polyposis, Peutz-Jeghers syndrome, and juvenile polyposis also predispose to CRC.

Genetic testing is available, and screening for cancer in HNPCC and FAP should begin during childhood or adolescence. Likewise, genetic evaluation for these conditions should be pursued in young patients presenting with colon cancer, even when there is no history of predisposing genetic conditions.

Presenting symptoms include bloody stools or melena, abdominal pain, weight loss, and changes in bowel patterns. In many cases, signs are vague, often resulting in a delay in diagnosis, sometimes not until the disease has reached an advanced stage. The histologic subtype differs from that seen in adults, with the majority of pediatric tumors being either mucinous adenocarcinoma or signet ring cell carcinoma. Treatment consists of surgical resection when possible, with chemotherapy for unresectable tumors. Adequate lymph node removal should be performed at the time of surgical resection of primary tumor. Radiation therapy is useful in the treatment of rectal carcinomas.

506.5 Adrenal Tumors

Steven G. Waguespack

See Chapters 579 to 581.

Adrenocortical tumors (ACTs) arise from the outer adrenal cortex, whereas pheochromocytomas (PHEOs) derive from the catecholamine-producing chromaffin cells of the adrenal medulla. When catecholamine-producing tumors arise outside of the adrenal medulla, they are called paragangliomas (PGLs). The pathologic categorization of these tumors as benign or malignant does not always correlate well with the clinical behavior, making it difficult to differentiate malignant from benign disease based upon pathology alone. Hence, long-term follow-up is warranted. Because of the greater association with genetic disease, genetic counseling is also advised for all children diagnosed with an ACT or PHEO/PGL.

ACTs are very rare and tend to present before age 5 yr. They have a female predominance and are functional tumors in >90% of cases, primarily producing androgens and causing clinically apparent virilization. ACT may also present as an abdominal mass or pain. In children, ACTs are associated with Li-Fraumeni syndrome (germline inactivating mutations in the *TP53* tumor-suppressor gene), Beckwith-Wiedemann syndrome, hemihyperplasia other than that seen as part of Beckwith-Wiedemann syndrome, and, very rarely, congenital adrenal hyperplasia. Other unusual causes of nodular adrenocortical disease, which usually present with Cushing syndrome, include the Carney complex and macronodular adrenal hyperplasia.

PHEOs/PGLs are rare tumors that are more likely to be bilateral, malignant, and secondary to a heritable tumor syndrome when diagnosed in children. von Hippel–Lindau disease is the most common genetic cause of PHEOs/PGLs in the pediatric population, followed by the familial PGL syndromes caused by mutations in the succinate dehydrogenase gene. MEN2 (types 2A and 2B) and neurofibromatosis type 1 are also in the differential diagnosis, but are mostly associated with a PHEO diagnosis during adulthood. Although hypertension is usually paroxysmal in adults with PHEO, hypertension is usually sustained in children, who may also lack the typical triad of headache, palpitations, and diaphoresis seen commonly in adults. The best screening test for PHEO/PGL is measurement of plasma and/or urine metanephrine levels.

The initial treatment of ACT and PHEO/PGL is surgery. Children with PHEO/PGL require **preoperative medical management**, typically with α and β blockade. First-line medical therapy for metastatic ACT includes mitotane and chemotherapy with cisplatin, etoposide, and doxorubicin. Metastatic PHEO/PGL has historically been treated with cyclophosphamide, vincristine, and dacarbazine. In cases of both ACT and PHEO/PGL, novel targeted agents are being studied for the treatment of advanced metastatic disease, which is typically nonresponsive to standard chemotherapeutic approaches. Endocrine therapy targeting hormonal overproduction may also be needed to palliate symptoms and improve quality of life.

506.6 Desmoplastic Small Round Cell Tumor

Nidale Tarek and Cynthia E. Herzog

Desmoplastic small round cell tumor is a very rare and aggressive mesenchymal tumor that occurs predominantly in adolescent and young adult males. It is associated with a diagnostic chromosomal translocation between the Ewing tumor gene and the Wilms tumor gene, t(11;22)(p13;q12). Patients typically present with a bulky abdominal mass, multiple peritoneal and omental implants, and symptoms of abdominal sarcomatosis, including pain, ascites, intestinal obstruction, hydronephrosis, and weight loss. Desmoplastic small round cell tumor mainly involves the abdominal cavity but can spread to the lymph nodes, liver, lungs, and bones. Aggressive treatment with combination chemotherapy, debulking surgery, and whole abdominopelvic irradiation results almost universally in a poor outcome. Median survival ranges between 17 and 25 mo, and the 5 yr overall survival remains less than 20%. Alternative treatment options currently under investigation include hyperthermic intraperitoneal chemotherapy and radioimmunotherapy with monoclonal antibodies targeting different surface antigens on tumor cells.

Chapter 507

Histiocytosis Syndromes of Childhood

Stephan Ladisch

The childhood histiocytoses constitute a diverse group of disorders, which, although individually rare, are frequently severe in their clinical expression. These disorders are grouped together because they have in common a prominent proliferation or accumulation of cells of the monocyte–macrophage system of bone marrow origin. Although these disorders sometimes are difficult to distinguish clinically, accurate diagnosis is essential nevertheless for facilitating progress in treatment. A systematic classification of the childhood histiocytoses is based on histopathologic findings (Table 507-1). A thorough, comprehensive evaluation of a biopsy specimen obtained at the time of diagnosis is essential. This evaluation includes studies such as electron microscopy and immunostaining that may require special sample processing.

CLASSIFICATION AND PATHOLOGY

Three classes of childhood histiocytosis are defined, based on histopathologic findings. The most well-known childhood histiocytosis, **Langerhans cell histiocytosis (LCH)**, previously known as **histiocytosis X,** includes the clinical entities of eosinophilic granuloma, **Hand-Schüller-Christian disease,** and **Letterer-Siwe disease.** The normal Langerhans cell is an antigen-presenting cell of the skin. The hallmark of LCH in all forms is the presence of a clonal proliferation of cells of the monocyte lineage containing the characteristic electron microscopic findings of a Langerhans cell. This is the **Birbeck granule,** a tennis racket–shaped bilamellar granule that, when seen in the cytoplasm of lesional cells in LCH, is diagnostic of the disease. The Birbeck granule expresses a newly characterized antigen, langerin (CD207), which is involved in antigen presentation to T lymphocytes. CD207 expression has been established to be uniformly present in LCH lesions and thus becomes an additional reliable diagnostic marker. It appears more likely that the LCH cell is not actually a (differentiated) Langerhans cell but rather an immature cell of myeloid origin, possibly in an arrested state of development. Nevertheless, the definitive diagnosis of LCH is established by demonstrating CD1a-positivity of lesional cells, which is done using fixed tissue (Fig. 507-1). Lesional cells must be distinguished from normal Langerhans cells of the skin, which are also CD1a-positive but are not diagnostic of LCH. The lesions may contain various proportions of these Langerhans granule-containing CD1a-positive cells, lymphocytes, granulocytes, monocytes, and eosinophils.

In contrast to the prominence of an antigen-presenting cell in LCH, the other common group of histiocytoses are nonmalignant proliferative disorders that are characterized by accumulation of activated antigen-processing cells (macrophages and lymphocytes). These are known as the **hemophagocytic lymphohistiocytoses (HLHs).** They are the result of uncontrolled hemophagocytosis and uncontrolled activation (upregulation) of inflammatory cytokines with some similarities to the macrophage activation syndrome (see Table 155-5). Tissue infiltration by activated CD8 T lymphocytes, activated macrophages, and hypercytokinemia are classic features (Fig. 507-2). With the characteristic morphology of normal macrophages by light microscopy, these phagocytic cells (Fig. 507-1) are negative for the markers (Birbeck granules, CD1a-positivity, CD207-positivity) characteristic of LCH cells but are CD163-positive.

The 2 major forms of hemophagocytic lymphohistiocytosis have indistinguishable pathologic findings but are very important to distinguish from one another because of implications for both treatment and for prognosis. One is **familial hemophagocytic lymphohistiocytosis (FHLH),** originally named **familial erythrophagocytic lymphohistiocytosis,** which is an autosomal recessive disorder and represents approximately 25% of patients with HLH. Genes are known for 4 of the 5 FHLH syndromes; these mutations affect the ability of T lymphocytes and natural killer cells to synthesize and release perforin and granzymes, thus reducing cytotoxic granule formation. The other is the **infection-associated hemophagocytic syndrome,** also called secondary hemophagocytic lymphohistiocytosis (Table 507-2). Both

Table 507-1 Classification of the Childhood Histiocytoses

	DISEASE	CELLULAR CHARACTERISTICS OF LESIONS	TREATMENT
LCH	Langerhans cell histiocytosis	Langerhans-like cells (CD1a-positive, CD207-positive) with Birbeck granules (LCH cells)	Local therapy for isolated lesions; chemotherapy for disseminated disease
HLH	Familial hemophagocytic lymphohistiocytosis Infection-associated hemophagocytic syndrome† Associated with albinism syndromes* Associated with immunocompromised states Associated with autoimmune/autoinflammatory states	Morphologically normal reactive macrophages with prominent erythrophagocytosis, and CD8-positive T cells	Chemotherapy; allogeneic bone marrow transplantation
Other	Juvenile xanthogranuloma	Characteristic vacuolated lesional histiocytes with foamy cytoplasm	None or excisional biopsy for localized disease; chemotherapy, radiotherapy for disseminated disease
	Rosai-Dorfman disease	Hemophagocytic histiocytes	None if localized; surgery for bulk reduction; chemotherapy if organ systems involvement
	Malignant histiocytosis	Neoplastic proliferation of cells with characteristics of monocytes/macrophages or their precursors	Antineoplastic chemotherapy, including anthracyclines
Other	Acute monocytic leukemia‡	M5 by FAB classification	Antineoplastic chemotherapy

*Chediak-Higashi and Hermansky-Pudlak syndromes.
†Also called secondary hemophagocytic lymphohistiocytosis.

From Nathan DG, Orkin SH, Ginsburg D, et al, editors: Nathan and Oski's hematology of infancy and childhood, *ed 6, Philadelphia, 2003, WB Saunders, p. 1381.*

diseases are characterized by disseminated lesions that involve many organ systems. The lesions are characterized by infiltration of the involved organ with activated phagocytic macrophages and lymphocytes, in which the lymphocyte defects (cytolytic pathway) are considered to be the primary abnormality.

Noninfectious causes that may trigger secondary HLH include drugs (phenytoin, highly active antiretroviral therapy), bone marrow transplantation, chemotherapy, autoimmune diseases, inflammatory bowel disease, and immunodeficiency states (DiGeorge syndrome, Bruton agammaglobulinemia, severe combined immunodeficiency syndrome, chronic granulomatous disease, cancer).

These diseases together comprise **HLH** (Table 507-3 and Fig. 507-3). Multiple different steps in granule formation and release by cytotoxic T cells, when inhibited by genetic mutation, can result in primary HLH (Fig. 507-3, bottom). In an analogous way, a trigger (e.g., infection) can result in secondary HLH (Fig. 507-3, top).

The mixed cellular lesions of both LCH and HLH are increasingly believed to point to these being disorders of immune regulation resulting from either an unusual and unidentified antigenic stimulation and/or an abnormal and defective cellular immune response. Mutations in the perforin (*PRF1*) gene or the *MUNC13-4* gene are the most common causes of defective function of the cytotoxic lymphocytes whose activity is inhibited in FHLH. Some cases of LCH demonstrate clonality of individual lesions. In LCH, a mutated form of the *BRAF* gene has been identified in many patients; its pathophysiologic significance is being

Table 507-3	Classification of Primary HLH, Notable Clinical Findings, and Rapid Diagnostic Results			
	DEFECTIVE GENE	**FUNCTION**	**NOTABLE CLINICAL FINDINGS**	**RAPID DIAGNOSIS BY FLOW CYTOMETRY**
HLH TYPE

‡Defect is present in all tissues.

AR, autosomal recessive; CNS, central nervous system; FHLH, familial hemophagocytic lymphohistiocytosis; HLH, hemophagocytic lymphohistiocytosis; IL, interleukin; NA, not available; NF-κB, nuclear factor kappa light chain enhancer of activated B cells; NK, natural killer; SAP, signaling lymphocyte-activating molecule–associated protein; XIAP, X-linked inhibitor of apoptosis protein; XLP, X-linked lymphoproliferative; XMEN, X-linked immunodeficiency with Mg^{2+} defect, Epstein-Barr virus infection, and neoplasia.

(From Chandrakasan S, Filipovich AH. Hemophagocytic lymphohistiocytosis: advances in pathophysiology, diagnosis, and treatment. J Pediatr *163(5):1253-1259, 2013.)*

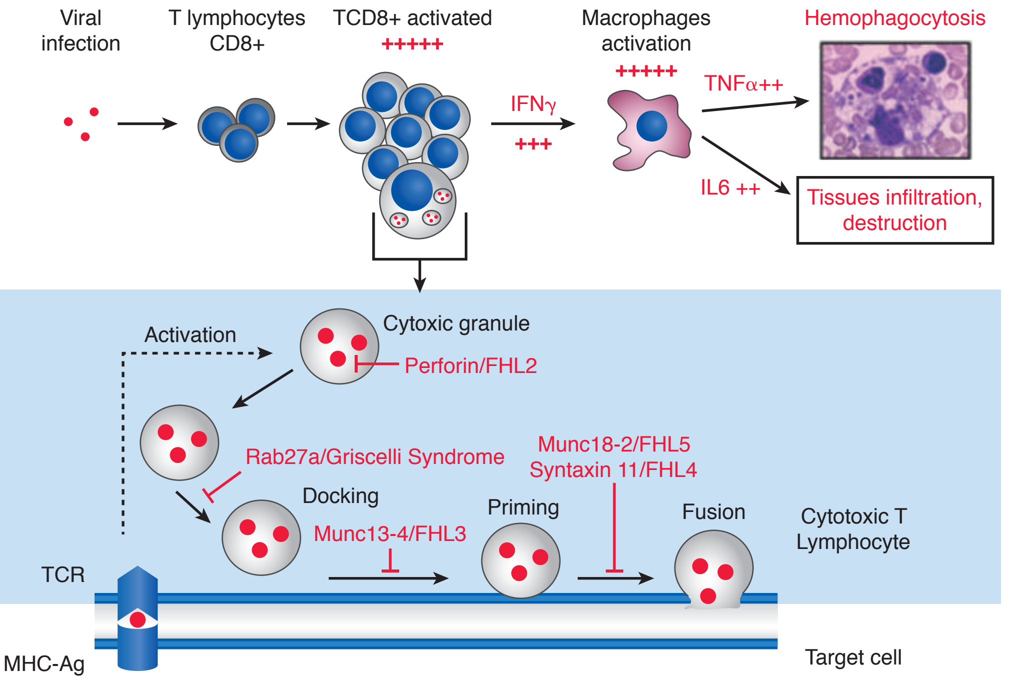

Figure 507-3 **Inborn errors in the cytotoxic activity of lymphocytes.** *Top:* Schematic diagram of the immune mechanisms leading to the occurrence of a hemophagocytic syndrome. Following a viral infection, antigen-specific $CD8^+$ T lymphocytes undergo massive expansion and activation and secrete high levels of interferon (IFN)-γ. The overwhelming activated effector cells induce excessive macrophage activation and pro-inflammatory cytokine production including tumor necrosis factor (TNF)-α and interleukin-6 (IL-6). Macrophages spontaneously phagocytose blood elements (here shown: platelets, red blood cells, and a polymorphonuclear cell). Activated lymphocytes and macrophages infiltrate various organs, resulting in massive tissue necrosis and organ failure. *Bottom:* The genetic defects causing hemophagocytic lymphohistiocytic syndrome (HLH) affect a precise step of the cytotoxic machinery, i.e. granule content, docking, priming, or fusion. Only the defects causing Griscelli syndrome (GS) and familial hemophagocytic lymphohistiocytosis (FHL) are shown. *(From Pachlopnik Schmid J, Cote M, Menager MM, et al: Inherited defects in cytotoxic lymphocyte activity.* Immunol Rev *235:10–23, 2010.)*

assessed. The *BRAF* mutation suggests both that there is an autonomous proliferative element to the disease and that there may potentially be a new avenue for therapeutic approaches.

In addition to these two most common forms of childhood histiocytosis, LCH and HLH, a number of rarer diseases are also included under this rubric, because they have in common various abnormalities of these cell populations of myeloid origin. These other diseases include **juvenile xanthogranuloma**, in which the lesional histiocytes are vacuolated, with foamy cytoplasm, and the lesions evolve into mixed granulomas also containing eosinophils, lymphocytes, and other cells. Another rare histiocytosis is **Rosai-Dorfman disease**, also known as **sinus histiocytosis** with massive lymphadenopathy. Packing of sinusoids of the lymph nodes with histiocytes that are hemophagocytic characterizes Rosai-Dorfman disease, although extranodal involvement is not uncommon. The etiology of these 2 diseases is unknown. Finally, there is also a group of unequivocal malignancies of cells of monocyte–macrophage lineage. By this definition, acute monocytic leukemia and true malignant histiocytosis are included among the class III histiocytoses (see Chapter 495). True neoplasms of Langerhans cells, while extremely rare, have been reported.

507.1 Langerhans Cell Histiocytosis

Stephan Ladisch

CLINICAL MANIFESTATIONS

LCH has an extremely variable presentation. The skeleton is involved in 80% of patients and may be the only affected site, especially in children older than 5 yr of age. Bone lesions may be single or multiple and are seen most commonly in the skull (Fig. 507-4). Other sites include the pelvis, femur, vertebra, maxilla, and mandible. They may be asymptomatic or associated with pain and local swelling. Involvement of the spine may result in collapse of the vertebral body, which can be seen radiographically, and may cause secondary compression of the spinal cord. In flat and long bones, osteolytic lesions with sharp borders occur and no evidence exists of reactive new bone formation until the lesions begin to heal. Lesions that involve weight-bearing long bones may result in pathologic fractures. Chronically draining, infected ears are commonly associated with destruction in the mastoid area. Bone destruction in the mandible and maxilla may result in teeth that, on radiographs, appear to be free floating. With response to therapy, healing may be complete.

Approximately 50% of patients experience skin involvement at some time during the course of disease, usually as a hard-to-treat scaly, papular, seborrheic dermatitis of the scalp, diaper, axillary, or posterior

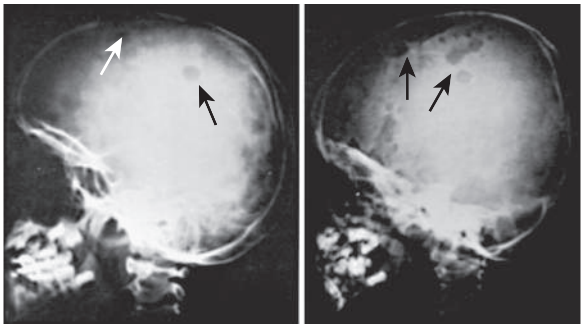

Figure 507-4 Two skull radiographs from patients with Langerhans cell histiocytosis (LCH). *Left,* The patient was older than 2 yr of age and had involvement limited to isolated bone lesions *(arrows).* She had a good recovery. *Right,* The patient was younger than 2 yr of age and had extensive bone disease *(arrows),* a febrile course, anemia, severe skin eruption, generalized lymphadenopathy, hepatosplenomegaly, pulmonary infiltrates, and a fatal outcome despite antitumor chemotherapy. These patients represent opposite ends of the clinical spectrum of LCH.

auricular regions. The lesions may spread to involve the back, palms, and soles. The exanthem may be petechial or hemorrhagic, even in the absence of thrombocytopenia. Localized or disseminated lymphadenopathy is present in approximately 33% of patients. Hepatosplenomegaly occurs in approximately 20% of patients. Various degrees of hepatic malfunction may occur, including jaundice and ascites.

Exophthalmos, when present, often is bilateral and is caused by retroorbital accumulation of granulomatous tissue. Gingival mucous membranes may be involved with infiltrative lesions that appear superficially like candidiasis. Otitis media is present in 30-40% of patients; deafness may follow destructive lesions of the middle ear. In 10-15% of patients, pulmonary infiltrates are found on radiography. The lesions may range from diffuse fibrosis and disseminated nodular infiltrates to diffuse cystic changes. Rarely, pneumothorax may be a complication. If the lungs are severely involved, tachypnea and progressive respiratory failure may result.

Pituitary dysfunction or hypothalamic involvement may result in growth retardation. In addition, patients may have diabetes insipidus; patients suspected of having LCH should demonstrate the ability to concentrate their urine before going to the operating room for a biopsy. Rarely, panhypopituitarism may occur. Primary hypothyroidism as a result of thyroid gland infiltration also may occur.

Patients with multisystem disease who are affected more severely are those who have systemic manifestations, including fever, weight loss, malaise, irritability, and failure to thrive. These systemic manifestations will distinguish between patients who are at high risk of mortality (i.e., "risk organ"-positive patients), and those without, who are at low risk (i.e., "risk organ"-negative patients). The risk organs are liver, spleen hematopoietic system, and lung. The distinction is important for deciding the intensity of the treatment approach and has been incorporated into standard treatment approaches for LCH, as delineated in the Histiocyte Society protocols. Bone marrow involvement may cause anemia and thrombocytopenia. Two uncommon but serious manifestations of LCH are hepatic involvement (leading to fibrosis and cirrhosis) and a peculiar central nervous system (CNS) involvement characterized by ataxia, dysarthria, and other neurologic symptoms. Hepatic involvement is associated with multisystem disease that is often already present at the time of diagnosis. In contrast, the CNS involvement, which is progressive and histopathologically characterized by gliosis, and for which no treatment is known, may be observed only many years after the initial diagnosis of LCH, which itself may have consisted only of mild bone disease. Neither of these manifestations evidences Langerhans cells or Birbeck granules, and both are suspected to be driven initially by cytokine abnormalities.

After tissue biopsy, which is diagnostic and is easiest to perform on skin or bone lesions, a thorough clinical and laboratory evaluation should be undertaken. This should include a series of studies in all patients (complete blood cell count, liver function tests, coagulation studies, skeletal survey, chest radiograph, and measurement of urine osmolality). In addition, detailed evaluation of any organ system that has been shown to be involved by physical examination or by these studies should be performed to establish the extent of disease before initiation of treatment.

TREATMENT AND PROGNOSIS

The clinical course of single-system disease (usually bone, lymph node, or skin) generally is benign, with a high chance of spontaneous remission. Therefore, treatment should be minimal and should be directed at arresting the progression of a bone lesion that could result in permanent damage before it resolves spontaneously. Curettage or, less often, steroid injection or low-dose local radiation therapy (5-6 Gy) may accomplish this goal. Multisystem disease, in contrast, should be treated with systemic multiagent chemotherapy. Several different regimens have been proposed, but central elements are the inclusion of vinblastine and steroids, both of which have been found to be very effective in treating LCH. Etoposide has more recently been excluded from standard treatment of multisystem LCH, while treatment of multisystem LCH includes therapy with multiple agents, designed to reduce mortality, reactivation of disease, and long-term consequences.

The response rate to therapy is now quite high, and mortality in severe LCH has been substantially reduced by multiagent chemotherapy, especially if the diagnosis is made accurately and expeditiously. The most recent treatment results, employing lengthened continuation therapy, show a greater than 85% survival rate in severe multisystem disease and a reduced rate of reactivation. Experimental therapies, suggested only for unresponsive disease (often in very young children with multisystem disease and organ dysfunction who have not responded to multiagent initial treatment), include immunosuppressive therapy with cyclosporine/antithymocyte globulin and possibly imatinib, 2-chlorodeoxyadenosine, and stem cell transplantation. Late (fibrotic) complications, whether hepatic or pulmonary, are irreversible and require organ transplantation to be definitively treated. Current treatment approaches and experimental protocols for both LCH and HLH can be obtained at the website for the Histiocyte Society (http://www.histiocytesociety.org). An unresolved problem is treatment of the (usually late-onset) severe, progressive, and intractable LCH-associated neurodegenerative syndrome.

507.2 Hemophagocytic Lymphohistiocytosis

Stephan Ladisch

(See "Classification and Pathology" above.)

CLINICAL MANIFESTATIONS

The major forms of HLH, FHLF and secondary HLH, have a remarkably similar presentation consisting of a generalized disease process, most often with fever (90-100%), maculopapular and/or petechial rash (10-60%), weight loss, and irritability (see Tables 507-4 and 507-5). FHLH also is characterized by severe immunodeficiency. Children with FHLH generally are younger than 4 yr of age, and children with secondary HLH may present at an older age, but both forms are recognized as presenting at any age. **Physical examination** often reveals hepatosplenomegaly (70-100%), lymphadenopathy (20-50%), respiratory distress (40-90%), jaundice, and symptoms of CNS involvement (~50%) that are not unlike those of aseptic meningitis or acute demyelinating encephalomyelitis (see Chapter 600.3). MRI may demonstrate systemic T2-weighted/FLAIR hyperintensities in gray and white matter and in supratentorial and infratentorial regions. The cerebrospinal fluid pleocytosis (50-90%) in CNS involvement of FHLH is characterized by cells that are the same phagocytic macrophages found in the peripheral blood or bone marrow. The **diagnosis** can be made either on the basis of a molecular (genetic) defect (see "Treatment and Prognosis" below) or on the pathologic findings of hemophagocytosis in bone marrow biopsy, and is suggested by clinical findings of fever, splenomegaly, and associated laboratory findings (in both forms of HLH), including hypertriglyceridemia (80-100%), hypofibrinogenemia (65-85%), elevated levels of hepatic enzymes (30-90%), extremely elevated levels of circulating soluble interleukin-2 receptors released by the activated lymphocytes, very high levels of serum ferritin (often >10,000), and cytopenias (in ~90-100%; especially pancytopenia from hemophagocytosis in the marrow). Hemophagocytosis is not specific for HLH without other features. In addition, in some subgroups of HLH perforin assays may be normal. In the absence of genetic mutations, the diagnosis of HLH is based on a set of specific criteria formulated by the Histiocyte Society, the presence of 5 of 8 of which is considered diagnostic of HLH (see Table 507-4): fever, splenomegaly, cytopenia of 2 cell lines, hypertriglyceridemia or hypofibrinogenemia, hyperferritinemia, elevated soluble CD25 (interleukin-2 receptor), reduced or absent natural killer cells, and bone marrow, cerebrospinal fluid, or lymph node evidence of hemophagocytosis. There are patients with FHLH who have no known identifiable gene mutation. No absolute clinical or laboratory distinction can be made between FHLH and secondary HLH, although genetic markers for FHLH can complement a positive family history for other affected children.

In the absence of either (1) documented genetic defect coupled with defective NK cell cytotoxicity or (2) frank hemophagocytosis, great care should be taken in making the diagnosis of (secondary) HLH, with its implication of the use of cytotoxic chemotherapy. This is because the otherwise nonspecific criteria (indicative of inflammation) used to diagnose HLH can also be seen in diseases that are not always associated with hemophagocytosis (such as an overwhelming acute viral infection without T cell overactivation) in which the cytotoxic and immunosuppressive therapy used in treating HLH might be contraindicated.

TREATMENT AND PROGNOSIS

The diagnostic distinction between FHLH and secondary HLH sometimes can be based on the acute onset of secondary HLH in the presence of a documented infection. In this case, treatment of the underlying infection, coupled with supportive care, is critical. If the diagnosis is made in a setting of iatrogenic immunodeficiency, immunosuppressive treatment should be withdrawn and supportive care should be instituted along with specific therapy for underlying infection. When FHLH (gene mutations in perforin or Munc13-4 proteins) is diagnosed or is suspected together with no documentation of an infection, therapy currently includes etoposide, corticosteroids, and intrathecal methotrexate. It should be stressed that pancytopenia is not a

Table 507-4	Diagnostic Guidelines for Hemophagocytic Lymphohistiocytosis

The diagnosis of HLH is established by fulfilling one of the following two criteria:

1. A molecular diagnosis consistent with HLH (e.g., PRF mutations, SAP mutations)

or

2. Having 5 of the following 8 signs or symptoms:
   a. Fever
   b. Splenomegaly
   c. Cytopenia (affecting ≥2 cell lineages; hemoglobin ≤9 g/dL [or ≤10 g/dL for infants <4 wk of age], platelets <100,000/µL, neutrophils <1,000/µL)
   d. Hypertriglyceridemia (≥265 mg/dL) and/or hypofibrinogenemia (≤150 mg/dL)
   e. Hemophagocytosis in the bone marrow, spleen, or lymph nodes without evidence of malignancy
   f. Low or absent natural killer cell cytotoxicity
   g. Hyperferritinemia (≥500 ng/mL)
   h. Elevated soluble CD25 (interleukin-2Rα chain; ≥2,400 U/mL)

contraindication to cytotoxic therapy in FHLH. Some recommend antithymocyte globulin and cyclosporine for maintenance therapy. Nevertheless, even with chemotherapy, FHLH remains ultimately fatal, often after a relapse of the disease. Allogeneic **stem cell transplantation** is effective in curing approximately 60% of patients with FHLH.

In contrast, in secondary HLH, it is critical that the underlying disease (e.g., infection, malignancy, or other) be identified and successfully treated. In many cases, such as when an infection can be documented and effectively treated, the prognosis may be excellent without any other specific treatment. However, when a treatable infection or other cause cannot be documented, which is the case in many patients presumed to have secondary HLH, the prognosis may be as poor as that of FHLH, and an identical chemotherapeutic approach, including etoposide, is recommended, even in the face of cytopenias. It is theorized that in both cases, by its cytotoxic effect on macrophages, etoposide interrupts cytokine production, the hemophagocytic process, and the accumulation of macrophages, all of which may contribute to the pathogenesis of infection-associated hemophagocytic syndrome. A broad spectrum of infectious agents, including viruses (e.g., cytomegalovirus, Epstein-Barr virus, human herpesvirus 6), fungi, protozoa, and bacteria, may trigger secondary HLH, often in the setting of immunodeficiency (see Table 507-2). A thorough evaluation for infection should be undertaken in immunodeficient patients with hemophagocytosis. The same syndrome may be identified in conjunction with a rheumatologic disorder (e.g., systemic lupus erythematosus, Kawasaki disease) or a neoplasm (leukemia); in these cases, effective treatment of the underlying disease may cause resolution of the hemophagocytosis. In some patients, interferon and intravenous immunoglobulin have been effective.

507.3 Other Histiocytoses

Stephan Ladisch

Other rare histiocytoses are appropriately named for their clinical presentation. Examples include xanthogranuloma in juvenile xanthogranuloma and striking lymphadenopathy in Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy). Juvenile xanthogranuloma may require systemic treatment with cytotoxic chemotherapy if the disease is disseminated. Rosai-Dorfman disease is usually not treated, although the massive lymphadenopathy may require treatment because of its tendency to cause physical obstruction. Acute monocytic leukemia and true malignant histiocytosis are included because they are unequivocal malignancies of the monocyte-macrophage lineage; they are discussed in Chapter 490.

Nephrology

PART XXIII

Section 1
Glomerular Disease

Chapter 508
Introduction to Glomerular Diseases

508.1 Anatomy of the Glomerulus

Cynthia G. Pan and Ellis D. Avner

The kidneys lie in the retroperitoneal space slightly above the level of the umbilicus. They range in length and weight, respectively, from approximately 6 cm and 24 g in a full-term newborn to ≥12 cm and 150 g in an adult. The kidney (Fig. 508-1) has an outer layer, **the cortex**, which contains the glomeruli, proximal and distal convoluted tubules, and collecting ducts; and an inner layer, **the medulla**, that contains the straight portions of the tubules, the loops of Henle, the vasa recta, and the terminal collecting ducts (Fig. 508-2).

The blood supply to each kidney usually consists of a main renal artery that arises from the aorta; multiple renal arteries can occur. The main artery divides into segmental branches within the medulla, becoming the interlobar arteries that pass through the medulla to the corticomedullary junction. At this point, the interlobar arteries branch to form the arcuate arteries, which run parallel to the surface of the kidney. Interlobular arteries originate from the arcuate arteries and give rise to the afferent arterioles of the glomeruli. Specialized muscle cells in the wall of the afferent arteriole and specialized distal tubular cells adjacent to the glomerulus (macula densa) form the juxtaglomerular apparatus that controls the secretion of renin. The afferent arteriole divides into the glomerular capillary network, which then recombines into the efferent arteriole (see Fig. 508-2). The juxtamedullary efferent arterioles are larger than those in the outer cortex and provide the blood supply, as the vasa recta, to the tubules and medulla.

Each kidney contains approximately 1 million nephrons (each consisting of a glomerulus and associated tubules). There is a large distribution of "normal nephron number" in humans, with the mean ±2 SD ranging from 200,000 to 2 million nephrons/kidney. This variation can have major pathophysiologic significance as a risk factor for the later development of hypertension and progressive renal dysfunction. In humans, formation of nephrons is complete at 36-40 wk of gestation, but functional maturation with tubular growth and elongation continues during the 1st decade of life. Because new nephrons cannot be formed after birth, any disease that results in progressive loss of nephrons can lead to renal insufficiency. A decreased number of nephrons secondary to low birthweight, prematurity, and/or unknown genetic or environmental factors has been implicated as a significant risk factor for the development of primary hypertension and progressive renal dysfunction in adulthood. Low nephron number presumably results in hyperfiltration and eventual sclerosis of "overworked" nephron units.

The glomerular network of specialized capillaries serves as the filtering mechanism of the kidney. The glomerular capillaries are lined by endothelial cells (Fig. 508-3) and have very thin cytoplasm that contains many holes (fenestrations). The glomerular basement membrane (GBM) forms a continuous layer between the endothelial and mesangial cells on one side and the epithelial cells on the other. The membrane has 3 layers: a central electron-dense lamina densa; the lamina rara interna, which lies between the lamina densa and the endothelial cells; and the lamina rara externa, which lies between the lamina densa and the epithelial cells. The visceral epithelial cells cover the capillary and project cytoplasmic foot processes, which attach to the lamina rara externa. Between the foot processes are spaces or filtration slits. The

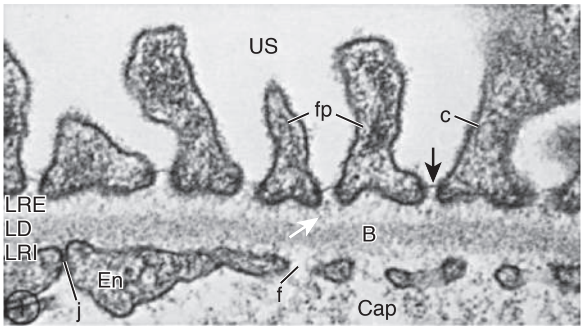

Figure 508-3 Electron micrograph of the normal glomerular capillary (Cap) wall demonstrating the endothelium (En) with its fenestrations (f), the glomerular basement membrane (B) with its central dense layer, the lamina densa (LD), and adjoining lamina rara interna (LRI) and externa (LRE) (*white arrow*), and the epithelial cell foot processes (fp) with their thick cell coat (c). The glomerular filtrate passes through the endothelial fenestrae, crosses the basement membrane, and passes through the filtration slits (*black arrow*) between the epithelial cell foot processes to reach the urinary space (US) (×60,000). J is the junction between 2 endothelial cells. *(From Farquhar MG, Kanwar YS: Functional organization of the glomerulus: state of the science in 1979. In Cummings NB, Michael AF, Wilson CB, editors:* Immune mechanisms in renal disease, *New York, 1982, Plenum.)*

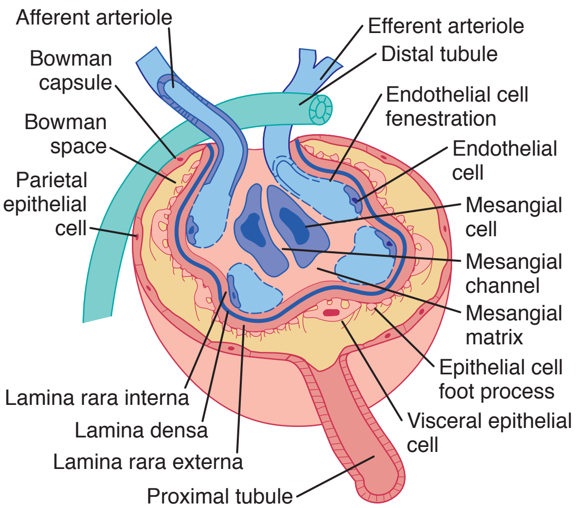

Figure 508-4 Schematic depiction of the glomerulus and surrounding structures.

mesangium (mesangial cells and matrix) lies between the glomerular capillaries on the endothelial cell side of the GBM and forms the medial part of the capillary wall. The mesangium may serve as a supporting, stalk-like structure for the glomerular capillaries and probably has a role in the regulation of glomerular blood flow, filtration, and the removal of macromolecules (such as immune complexes) from the glomerulus. Bowman's capsule, which surrounds the glomerulus, is composed of a basement membrane, which is continuous with the basement membranes of the glomerular capillaries and the proximal tubules, and the parietal epithelial cells, which are adjacent to the visceral epithelium (Fig. 508-4).

Bibliography is available at Expert Consult.

508.2 Glomerular Filtration

Cynthia G. Pan and Ellis D. Avner

Kidney function is best measured as glomerular filtration rate (GFR). As the blood passes through the glomerular capillaries, the plasma is filtered through the glomerular capillary walls. The ultrafiltrate, which is cell free, contains all of the substances in plasma (electrolytes, glucose, phosphate, urea, creatinine, peptides, low-molecular-weight proteins) except proteins having a molecular weight of ≥68 kDa (such as albumin and globulins). The filtrate is collected in Bowman's space and enters the tubules. There its composition is modified by tightly regulated secretion and absorption of solute and fluid by the multiple tubular segments of the nephron and the ductal system, until it exits the kidney, via the ureter, as urine.

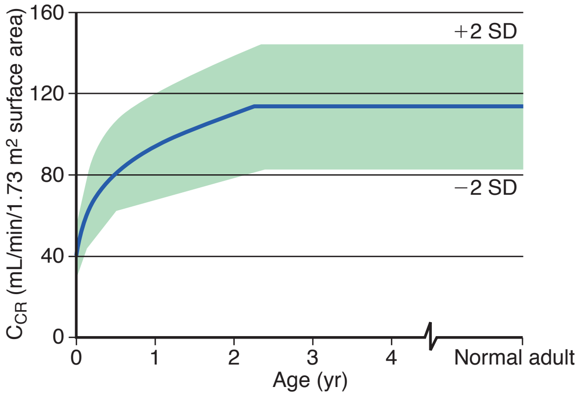

Figure 508-5 Changes in the normal value of the glomerular filtration rate, as measured by the creatinine clearance (Ccr), when standardized to mL/min/1.73 m^2 of body surface area. The *solid line* depicts the mean, and the *shaded area* includes 2 SD. *(From McCrory W: Developmental nephrology, Cambridge, MA, 1972, Harvard University Press.)*

Glomerular filtration is the net result of opposing forces applied across the capillary wall. The force for ultrafiltration (glomerular capillary hydrostatic pressure) is a result of systemic arterial pressure, modified by the tone of the afferent and efferent arterioles. The major force opposing ultrafiltration is glomerular capillary oncotic pressure, created by the gradient between the high concentration of plasma proteins within the capillary and the almost protein-free ultrafiltrate in Bowman's space. Filtration may be modified by the rate of glomerular plasma flow, the hydrostatic pressure within Bowman's space, and/or the permeability of the glomerular capillary wall.

Although glomerular filtration begins at approximately the 6th wk of fetal life, kidney function is not necessary for normal intrauterine homeostasis because the placenta serves as the major fetal excretory organ. After birth, the GFR increases until renal growth ceases (by age ~18-20 yr in most people). To compare GFRs of children and adults, the GFR is standardized to the body surface area (1.73 m^2) of an "ideal" 70-kg adult. Even after correction for surface area, the GFR of a child does not approximate adult values until the 3rd yr of life (Fig. 508-5). The GFR may be estimated by measurement of the serum creatinine level. Creatinine is derived from muscle metabolism. Its production is relatively constant, and its excretion is primarily through glomerular filtration, although tubular secretion can become important as serum creatinine rises in renal insufficiency. In contrast to the concentration of blood urea nitrogen, which is affected by state of hydration and nitrogen balance, the serum creatinine level is primarily influenced by muscle mass and the level of glomerular function. The serum creatinine is of value only in estimating the GFR under steady-state conditions. A patient can have a normal serum creatinine level without effective renal function very shortly after the onset of acute renal failure with anuria. In this clinical setting, serum creatinine is an insensitive measure of decreased renal function because its level does not rise above normal until GFR falls by 30-40%.

The precise measurement of the GFR is accomplished by quantitating the clearance of a substance that is freely filtered across the capillary wall and is neither reabsorbed nor secreted by the tubules. The clearance (C_s) of such a substance is the volume of plasma that, when completely cleared of the contained substance, would yield an equal

quantity of that substance excreted in the urine over a specified time. Renal clearance is calculated by the following formula:

$$C_s\,(\text{mL/min}) = U_s(\text{mg/mL}) \times V\,(\text{mL/min})/P_s(\text{mg/mL})$$

where C_s equals the clearance of substance s, U_s reflects the urinary concentration of s, V represents the urinary flow rate, and P_s equals the plasma concentration of s. To correct the clearance for individual body surface area, the formula is:

$$\text{Corrected clearance}\,(\text{mL/min/1.73 m}^2) = C_s(\text{mL/min}) \times \frac{1.73}{\text{Surface area}\,(\text{m}^2)}$$

The GFR is optimally measured by the clearance of inulin, a fructose polymer having a molecular weight of approximately 5 kDa. Because the inulin clearance technique is cumbersome for use in clinical practice, the GFR is commonly estimated by the clearance of endogenous creatinine. Formulas that estimate creatinine clearance accurately in clinical settings have been useful tools in patient care. The "bedside" Schwartz formula is the most widely used pediatric formula and is based on the serum creatinine, patient height, and an empirical constant. The accuracy of this equation is further improved utilizing an additional endogenous marker, cystatin C, in addition to serum creatinine. Cystatin C is a 13.6 kDa protease inhibitor produced by nucleated cells. It continues to be tested as a clinical tool to completely replace creatinine-based formulas, as it has distinct advantages in estimating GFR. Unlike creatinine, cystatin C is unaffected by sex, height, muscle mass, bilirubin, or red blood cell hemolysis, and is not secreted by the renal tubules under any conditions.

The absence of plasma proteins larger than the size of albumin from the glomerular filtrate confirms the effectiveness of the glomerular capillary wall as a filtration barrier. Major factors restricting the filtration of these and other macromolecules include their size and their ionic charge. Morphologic studies suggest that the size-selective filtration barrier resides within the GBM. The endothelial cell, basement membrane, and epithelial cell of the glomerular capillary wall all possess strong negative ionic charges (heparan sulfate and glycoproteins containing sialic acid). Proteins in the blood have a relatively low isoelectric point, carry a net negative charge, and are repelled by the negatively charged sites of the glomerular capillary wall, thus restricting filtration.

508.3 Glomerular Diseases

Cynthia G. Pan and Ellis D. Avner

PATHOGENESIS

Glomerular injury may be a result of genetic, immunologic, perfusion, or coagulation disorders. Genetic disorders of the glomerulus may result from mutations in DNA exons encoding proteins located within the glomerulus, interstitium, or tubular epithelium; mutations in regulatory genes controlling DNA transcription; abnormal posttranscriptional modification of RNA transcripts; or abnormal posttranslational modification of proteins. Immunologic injury to the glomerulus results in **glomerulonephritis,** which is a generic term for several diseases, but more precisely a histopathologic term defining inflammation of the glomerular capillaries. Evidence that glomerulonephritis is caused by immunologic injury includes morphologic and immunopathologic similarities to experimental immune-mediated glomerulonephritis; the demonstration of immune reactants (immunoglobulin, complement) in glomeruli; abnormalities in serum complement; and the finding of autoantibodies (anti-GBM) in some of these diseases (Fig. 508-6). There appear to be 2 major mechanisms of immunologic injury: glomerular deposition of circulating antigen–antibody immune complexes and interaction of antibody with glomerular antigens in situ. In the latter circumstance, the antigen may be a normal component of the glomerulus (the noncollagenous domain [NC-1] of type IV

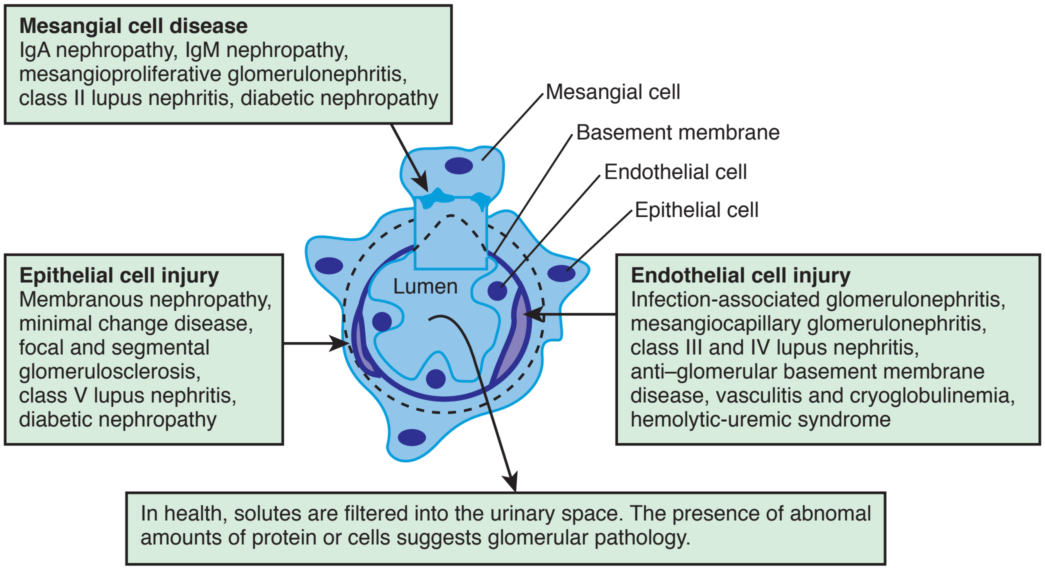

Figure 508-6 Cellular location of injury during glomerulonephritis. Mesangial cells are directly exposed to the circulation. Deposition of immune complexes within these cells is typically seen in disorders such as immunoglobulin A (IgA) nephropathy; it results in proliferation and expansion of the cells, leading to hematuria, proteinuria, and renal impairment. Epithelial cells, in conjunction with basement membrane, allow filtration of plasma solutes but retard passage of cells and plasma proteins. Disease related to these cells is typified by the presence of subepithelial deposits and flattening of the foot processes that engage the basement membrane, resulting in disruption of the filtration barrier and proteinuria. Endothelial cell disease can result from deposition of immune complex (as occurs in mesangiocapillary glomerulonephritis), attachment of antibody to the basement membrane (Goodpasture disease), or trauma and activation of coagulation (hemolytic-uremic syndrome). Endothelial cell proliferation and necrosis are accompanied by leukocyte accumulation, and rupture of the basement membrane, crescent formation, and disruption of glomerular architecture can develop. A nephritic or rapidly progressive presentation ensues. *(From Chadban SJ, Atkins RC: Glomerulonephritis,* Lancet *365:1797–1806, 2005.)*

collagen, a putative antigen in human anti-GBM nephritis) or an antigen that has been deposited in the glomerulus.

In **immune complex–mediated** diseases, antibody is produced against, and combines with, a circulating antigen that is usually unrelated to the kidney (see Fig. 508-6). The immune complexes accumulate in GBMs and activate the complement system, leading to immune injury. Acute serum sickness in rabbits is produced by a single intravenous injection of bovine albumin. Within 1 wk after injection, a rabbit produces antibody against bovine albumin, and the antigen remains in the blood in high concentration. As antibody enters the circulation, it forms immune complexes with antigen. Although the amount of antigen in the circulation exceeds that of antibody (antigen excess), the complexes formed are small, remain soluble in the circulation, and are deposited in glomeruli. The processes involved in glomerular localization are not well understood but include characteristics of the complex (concentration, charge, size) and/or the glomerulus (mesangial trapping, negatively charged capillary wall); hydrodynamic forces; and the influence of various chemical mediators (angiotensin II, prostaglandins).

With deposition of immune complexes in glomeruli, rabbits develop an acute proliferative glomerulonephritis. Immunofluorescence microscopy demonstrates granular **("lumpy-bumpy")** deposits containing immunoglobulin and complement in the glomerular capillary wall. Electron microscopic studies show these deposits to be on the epithelial side of the GBM and in the mesangium. For the next few days, as additional antibody enters the circulation, the antigen is ultimately removed from the circulation and the glomerulonephritis subsides.

An example of in situ antigen–antibody interaction is **anti–GBM antibody disease,** in which antibody reacts with antigen(s) of the GBM. Immunopathologic studies reveal linear deposition of immunoglobulin and complement along the GBM in Goodpasture syndrome (see Chapter 517) and certain types of rapidly progressive glomerulonephritis (see Chapter 516).

The inflammatory reaction that follows immunologic injury results from activation of 1 or more mediator pathways. The most important of these is the complement system, which has 2 initiating sequences: the classic pathway, which is activated by antigen–antibody immune complexes, and the alternative or properdin pathway, which is activated by polysaccharides and endotoxin. These pathways converge at C3; from that point on, the same sequence leads to lysis of cell membranes (see Chapter 133). The major noxious products of complement activation are produced after activation of C3 and include anaphylatoxin (which stimulates contractile proteins within vascular walls and increases vascular permeability) and chemotactic factors (C5a) that recruit neutrophils and perhaps macrophages to the site of complement activation, leading to consequent damage to vascular cells and basement membranes. Therapeutic agents to block the antibody production and components of the complement cascade are available and may provide additional tools to treat immune-mediated kidney injury (see Chapters 514 and 518).

The coagulation system may be activated **directly**, after endothelial cell injury that exposes the thrombogenic subendothelial layer (thereby initiating the coagulation cascade), or it may be activated **indirectly**, after complement activation. Consequently, fibrin is deposited within glomerular capillaries or within Bowman's space as crescents. Activation of the coagulation cascade can also activate the kinin system, which produces additional chemotactic and anaphylatoxin-like factors.

PATHOLOGY

The glomerulus may be injured by several mechanisms, but it has only a limited number of histopathologic responses; different disease states can produce similar microscopic changes.

Proliferation of glomerular cells occurs in most forms of glomerulonephritis and may be generalized (involving all glomeruli) or focal (involving only some glomeruli and sparing others). Within a single glomerulus, proliferation may be diffuse (involving all parts of the glomerulus) or segmental (involving only 1 or more tufts, but not others). Proliferation commonly involves the endothelial and mesangial cells and is often associated with an increase in the mesangial matrix (see Fig. 508-6). Mesangial proliferation can result from deposition of immune complex within the mesangium. The resultant increase in cell size and number, and production of mesangial matrix, can increase glomerular size and narrow the lumens of glomerular capillaries, leading to renal insufficiency.

Crescent formation in Bowman's space (capsule) is a result of proliferation of parietal epithelial cells and is often associated with clinical signs of renal dysfunction. Crescents develop in several forms of glomerulonephritis (termed **rapidly progressive** or **crescentic**; see Chapter 516) and are a characteristic response to deposition of fibrin in Bowman's space. Newly formed crescents contain fibrin, the proliferating epithelial cells of Bowman's space, basement membrane–like material produced by these cells, and macrophages that might have a role in the genesis of glomerular injury. Over the subsequent days to weeks, the crescent is invaded by connective tissue and becomes a fibroepithelial crescent. This process generally results in glomerular obsolescence and the clinical development of chronic renal failure. Crescent formation is often associated with glomerular cell death. The necrotic glomerulus has a characteristic eosinophilic appearance and usually contains nuclear remnants. Crescent formation is usually associated with generalized proliferation of the mesangial cells and with either immune complex or anti-GBM antibody deposition in the glomerular capillary wall.

Certain forms of acute glomerulonephritis show glomerular exudation of blood cells, including neutrophils, eosinophils, basophils, and mononuclear cells. The thickened appearance of GBM can result from a true increase in the width of the membrane (as seen in membranous glomerulopathy; see Chapter 512), from massive deposition of immune complexes that have staining characteristics similar to the membrane (as seen in systemic lupus erythematosus; see Chapter 514), or from the interposition of mesangial cells and matrix into the subendothelial space between the endothelial cells and the GBM. The last can give the basement membrane a split appearance, as seen in type I membranoproliferative glomerulonephritis (see Chapter 513) and other diseases.

Sclerosis refers to the presence of scar tissue within the glomerulus. Occasionally, pathologists use this term to refer to an increase in mesangial matrix.

Tubulointerstitial fibrosis is present in all patients who have glomerular disease and who develop progressive renal injury. This fibrosis is initiated by injury to either the glomeruli, which, if severe, may secondarily involve the tubules, or direct injury to the tubules themselves. Tubular injury recruits mononuclear cell infiltrate, which releases a variety of soluble factors that have fibrosis-promoting effects. Matrix proteins of the renal interstitium begin to accumulate, leading to eventual destruction of renal tubules and peritubular capillaries. The actual transformation of tubular epithelium to mesenchymal tissue can contribute to progressive tubulointerstitial fibrosis, a process termed *epithelial-mesenchymal transformation.*

Section 2
Conditions Particularly Associated with Hematuria

Chapter 509
Clinical Evaluation of the Child with Hematuria

Cynthia G. Pan and Ellis D. Avner

Hematuria is defined as the presence of at least 5 red blood cells (RBCs) per microliter of urine and occurs with a prevalence of 0.5-2.0% among school-age children. Quantitative studies demonstrate that normal children can excrete more than 500,000 RBCs per 12 hr period; this increases with fever and/or exercise. In the clinical setting, qualitative estimates are provided by a urinary dipstick that uses a very sensitive peroxidase chemical reaction between hemoglobin (or myoglobin) and a colorimetric chemical indicator impregnated on the dipstick. Chemstrip (Boehringer Mannheim), a common commercially available dipstick, is capable of detecting 3-5 RBCs/µL of unspun urine. The presence of 10-50 RBCs/µL may suggest underlying pathology, but significant hematuria is generally considered as >50 RBCs/µL. False-negative results can occur in the presence of formalin (used as a urine preservative) or high urinary concentrations of ascorbic acid (i.e., in patients with vitamin C intake >2000 mg/day). False-positive results may be seen in a child with an alkaline urine (pH > 8), or more commonly following contamination with oxidizing agents such as hydrogen peroxide used to clean the perineum before obtaining a specimen. Microscopic analysis of 10-15 mL of freshly voided and centrifuged urine is essential in confirming the presence of RBCs suggested by >10 RBCs/µL, or a 1+ positive urinary dipstick reading.

Red urine **without** RBCs is seen in a number of conditions (Table 509-1). Clinically significant heme-positive urine without RBCs may be caused by the presence of either hemoglobin or myoglobin. Hemoglobinuria without hematuria can occur in the presence of acute or chronic hemolysis. Myoglobinuria without hematuria occurs in the presence of rhabdomyolysis resulting from skeletal muscle injury and is generally associated with a 5-fold increase in the plasma concentration of creatinine kinase. **Rhabdomyolysis** is always clinically significant as it may lead to acute renal injury. It can occur secondary to viral myositis, crush injury, severe electrolyte abnormalities (hypernatremia, hypophosphatemia), hypotension, disseminated intravascular coagulation, toxins (drugs, venom), metabolic disorders of muscles, and prolonged seizures. Clinically innocuous heme-negative urine can appear red, cola colored, or burgundy, owing to ingestion of various drugs, foods (blackberries, beets), or dyes used in food and candy, whereas dark brown (or black) urine can result from various urinary metabolites.

Table 509-1 Other Causes of Red Urine	
HEME POSITIVE Hemoglobin Myoglobin	**Dyes (Vegetable/Fruit)** Beets Blackberries Food and candy coloring Rhubarb
HEME NEGATIVE **Drugs** Chloroquine Deferoxamine Ibuprofen Iron sorbitol Metronidazole Nitrofurantoin Phenazopyridine (Pyridium) Phenolphthalein Phenothiazines Rifampin Salicylates Sulfasalazine	**Metabolites** Homogentisic acid Melanin Methemoglobin Porphyrin Tyrosinosis Urates

Evaluation of the child with hematuria begins with a careful history, physical examination, and urinalysis. This information is used to determine the level of hematuria (upper vs lower urinary tract) and to determine the urgency of the evaluation based on symptomatology. Special consideration needs to be given to family history, identification of anatomic abnormalities and malformation syndromes, presence of gross hematuria, and manifestations of hypertension, edema, or heart failure.

Table 509-2 lists causes of hematuria. Upper urinary tract sources of hematuria originate within the nephron (glomerulus, tubular system, or interstitium). Lower urinary tract sources of hematuria originate from the pelvocaliceal system, ureter, bladder, or urethra. Hematuria from within the glomerulus is often associated with brown, cola- or tea-colored, or burgundy urine, proteinuria >100 mg/dL via dipstick, urinary microscopic findings of RBC casts, and deformed urinary RBCs (particularly acanthocytes). Hematuria originating within the tubular system may be associated with the presence of leukocytes or renal tubular casts. Lower urinary tract sources of hematuria may be associated with gross hematuria that is bright red or pink, terminal hematuria (gross hematuria occurring at the end of the urine stream), blood clots, normal urinary RBC morphology, and minimal proteinuria on dipstick (<100 mg/dL).

Patients with hematuria can present with a number of symptoms suggesting specific disorders. Tea- or cola-colored urine, facial or body edema, hypertension, and oliguria are classic symptoms of **glomerulonephritis.** Diseases commonly manifesting as glomerulonephritis include postinfectious glomerulonephritis, immunoglobulin A (IgA) nephropathy, membranoproliferative glomerulonephritis, Henoch-Schönlein purpura (HSP) nephritis, systemic lupus erythematosus (SLE) nephritis, granulomatosis with polyangiitis (formerly Wegener granulomatosis), microscopic polyarteritis nodosa, Goodpasture syndrome, and hemolytic-uremic syndrome. A history of recent upper respiratory, skin, or gastrointestinal infection suggests postinfectious glomerulonephritis, hemolytic-uremic syndrome, or HSP nephritis. Rash and joint complaints suggest HSP or SLE nephritis.

Hematuria associated with glomerulonephritis is typically painless, but can be associated with flank pain when acute or unusually severe. Frequency, dysuria, and unexplained fevers suggest a urinary tract infection, whereas renal colic suggests nephrolithiasis. A flank mass can suggest hydronephrosis, renal cystic diseases, renal vein thrombosis, or tumor. Hematuria associated with headache, mental status changes, visual changes (diplopia), epistaxis, or heart failure suggests significant hypertension. Patients with hematuria and a history of trauma require immediate evaluation (see Chapter 72). Child abuse must always be suspected in the child presenting with unexplained perineal bruising and hematuria.

A careful family history is critical in the initial assessment of the child with hematuria given the numerous genetic causes of renal disorders. Hereditary glomerular diseases include hereditary nephritis (Alport syndrome), thin glomerular basement membrane disease, SLE nephritis, and IgA nephropathy (Berger disease). Other hematuric renal disorders with a hereditary component include both autosomal recessive and autosomal dominant polycystic kidney

diseases, atypical hemolytic-uremic syndrome, urolithiasis, and sickle cell disease/trait.

A complete physical examination is critical to assess the cause of hematuria. Hypertension, edema, or signs of heart failure suggest acute glomerulonephritis. Several malformation syndromes are associated with renal disease including VATER (*v*ertebral body anomalies, *a*nal atresia, *t*racheo*e*sophageal fistula, and *r*enal dysplasia) syndrome. Abdominal masses may be caused by bladder distention in posterior urethral valves, hydronephrosis in ureteropelvic junction obstruction, polycystic kidney disease, or Wilms tumor. Hematuria seen in patients with neurologic or cutaneous abnormalities may be the result of a number of syndromic renal disorders including tuberous sclerosis, von Hippel-Lindau syndrome, and Zellweger (cerebrohepatorenal) syndrome. Anatomic abnormalities of the external genitalia may be associated with hematuria and/or renal disease.

Patients with gross hematuria present additional challenges because of the associated parental anxiety. The most common cause of gross hematuria is bacterial urinary tract infection. **Urethrorrhagia**, which is urethral bleeding in the absence of urine, is associated with dysuria and blood spots on underwear after voiding. This condition, which often occurs in prepubertal boys at intervals several months apart, has a benign self-limited course. Less than 10% of patients have evidence of glomerulonephritis. Recurrent episodes of gross hematuria suggest IgA nephropathy, Alport syndrome, or thin glomerular basement membrane disease. Dysuria and abdominal or flank pain are symptoms of idiopathic hypercalciuria, or urolithiasis. Table 509-3 lists common causes of gross hematuria; Figure 509-1 outlines a general approach to the laboratory and radiologic evaluation of the patient with glomerular or extraglomerular hematuria. Asymptomatic patients with isolated microscopic hematuria should not undergo extensive diagnostic evaluation, because such hematuria is often transient and benign.

ANA, antinuclear antibody; ASO, antistreptolysin O; BUN, blood urea nitrogen; C3/C4, complement; CBC, complete blood cell count; Cr, creatinine; RBC, red blood cell.

The child with completely asymptomatic isolated microscopic hematuria that persists on at least 3 urinalyses observed over a minimum of a 2 wk period poses a dilemma in regard to the degree of further diagnostic testing that should be performed. Significant disease of the urinary tract is uncommon with this clinical presentation. The initial evaluation of these children should include a urine culture followed by a spot urine for hypercalciuria with a calcium : creatinine ratio in culture-negative patients. In African-American patients, a sickle cell screen should be included. If these studies are normal, urinalysis of all first-degree relatives is indicated. Renal and bladder ultrasonography should be considered to rule out structural lesions such as tumor, cystic disease, hydronephrosis, or urolithiasis. Ultrasonography of the urinary tract is most informative in patients presenting with gross hematuria, abdominal pain, flank pain, or trauma. If these initial studies are normal, assessment of serum creatinine and electrolytes is recommended.

The finding of certain hematologic abnormalities can narrow the differential diagnosis. Anemia in this setting may be caused by hypervolemia with dilution associated with acute renal failure; decreased RBC production in chronic renal failure; hemolysis from hemolytic-uremic syndrome, a chronic hemolytic anemia, or SLE; blood loss from pulmonary hemorrhage, as seen in Goodpasture syndrome; or melena in patients with HSP or hemolytic-uremic syndrome. Inspection of the peripheral blood smear might reveal a microangiopathic process consistent with the hemolytic-uremic syndrome. The presence of autoantibodies in SLE can result in a positive Coombs test, the presence of antinuclear antibody, leukopenia, and multisystem disease. Thrombocytopenia can result from decreased platelet production (malignancies) or increased platelet consumption (SLE, idiopathic thrombocytopenic purpura, hemolytic-uremic syndrome, renal vein thrombosis, or congenital hepatic fibrosis with portal hypertension secondary to autosomal recessive polycystic kidney disease). Although urinary RBC morphology may be normal with lower tract bleeding and dysmorphic from glomerular bleeding, it is not sensitive enough to unequivocally delineate the site of hematuria. A bleeding diathesis is an unusual cause of hematuria. Coagulation studies are not routinely obtained unless personal or family history suggests a bleeding tendency.

A voiding cystourethrogram is only required in patients with a urinary tract infection, renal scarring, hydroureter, or pyelocaliectasis. Cystoscopy is an unnecessary and costly procedure in most pediatric patients with hematuria, and carries the associated risks of anesthesia. The diagnosis of "possible urethral stenosis" as an indication for cystoscopy should be viewed with a high degree of suspicion, because true urethral stenosis is quite rare. This procedure should be reserved for evaluating the rare child with a bladder mass noted on ultrasound, urethral abnormalities caused by trauma, posterior urethral valves, or tumor. The finding of unilateral gross hematuria localized by cystoscopy is rare, but it can indicate a vascular malformation or another anatomic abnormality.

Children with persistent asymptomatic isolated hematuria and a completely normal evaluation should have their blood pressure and urine checked every 3 mo until the hematuria resolves. Referral to a pediatric nephrologist should be considered for patients with persistent asymptomatic hematuria greater than 1 yr duration and is recommended for patients with nephritis (glomerulonephritis, tubulointerstitial nephritis), hypertension, renal insufficiency, urolithiasis or nephrocalcinosis, or a family history of renal disease such as polycystic kidney disease or hereditary nephritis. Renal biopsy is indicated for some children with persistent microscopic hematuria, and most children with recurrent gross hematuria associated with decreased renal function, proteinuria, or hypertension.

Chapter 510

Isolated Glomerular Diseases with Recurrent Gross Hematuria

Cynthia G. Pan and Ellis D. Avner

Approximately 10% of children with gross hematuria have an acute or a chronic form of glomerulonephritis that may be associated with a systemic illness. The gross hematuria, which is usually characterized by brown or cola-colored urine, may be painless or associated with vague flank or abdominal pain. Presentation with gross hematuria is common within 1-2 days after the onset of an apparent viral upper respiratory tract infection in immunoglobulin (Ig) A nephropathy, and typically resolves within 5 days. This relatively short period contrasts to a latency period of 7-21 days occurring between the onset of a streptococcal pharyngitis or impetiginous skin infection and the development of poststreptococcal acute glomerulonephritis. Gross hematuria in these circumstances can last as long as 4-6 wk. Gross hematuria can also be seen in children with glomerular basement membrane (GBM) disorders such as hereditary nephritis (Alport syndrome [AS]) and thin GBM disease. These glomerular diseases can also manifest as microscopic hematuria and/or proteinuria without gross hematuria.

510.1 Immunoglobulin A Nephropathy (Berger Nephropathy)

Cynthia G. Pan and Ellis D. Avner

IgA nephropathy is the most common chronic glomerular disease in children. It is characterized by a predominance of IgA within mesangial glomerular deposits in the absence of systemic disease. Diagnosis requires renal biopsy, which is performed when clinical features warrant confirmation of the diagnosis or characterization of the histologic severity, which might affect therapeutic decisions.

PATHOLOGY AND PATHOLOGIC DIAGNOSIS

Focal and segmental mesangial proliferation and increased mesangial matrix are seen in the glomerulus (Fig. 510-1). Renal histology

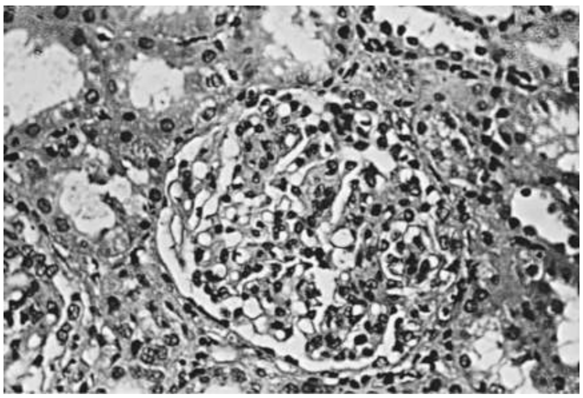

Figure 510-1 Light microscopy of IgA nephropathy demonstrating segmental mesangial proliferation and increased matrix (×180).

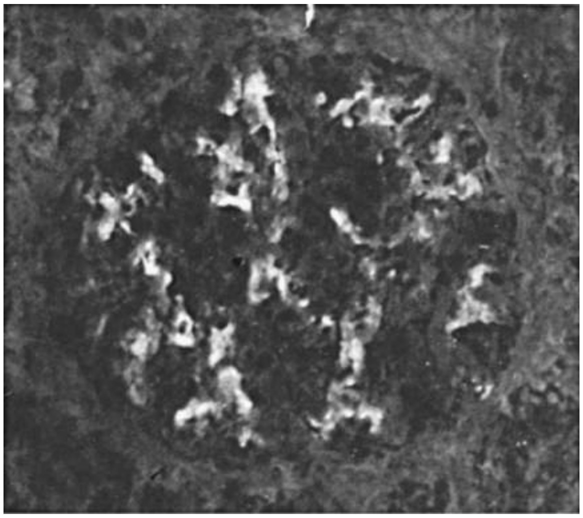

Figure 510-2 Immunofluorescence microscopy of the biopsy specimen from a child with episodes of gross hematuria demonstrating mesangial deposition of IgA (×150).

demonstrates mesangial proliferation that may be associated with epithelial cell crescent formation and sclerosis. IgA deposits in the mesangium are often accompanied by C3 complement (Fig. 510-2).

IgA nephropathy is an immune complex disease initiated by excessive amounts of poorly galactosylated IgA_1 in the serum causing the production of IgG and IgA autoantibodies. The abnormalities identified in the IgA system have also been observed in patients with Henoch-Schönlein purpura, and this finding lends support to the hypothesis that these 2 diseases are part of the same disease spectrum. Familial clustering of IgA nephropathy cases suggests the importance of genetic factors. Genome-wide linkage analysis suggests the linkage of IgA nephropathy to 6q22-23 in multiplex IgA nephropathy kindreds.

CLINICAL AND LABORATORY MANIFESTATIONS

IgA nephropathy is seen more often in male than in female patients. Although there are rare cases of rapidly progressive forms of the disease, the clinical presentation of childhood IgA nephropathy is often benign in comparison to that of adults. IgA nephropathy is an uncommon cause of end-stage renal failure during childhood. A majority of children with IgA nephropathy in the United States and Europe present with gross hematuria, whereas microscopic hematuria and/or proteinuria is a more common presentation in Japan. Other presentations include acute nephritic syndrome, nephrotic syndrome, or a combined nephritic-nephrotic picture. Gross hematuria often occurs within 1-2 days of onset of an upper respiratory or gastrointestinal infection, in contrast to the longer latency period observed in acute postinfectious glomerulonephritis, and may be associated with loin pain. Proteinuria is often <1000 mg/24 hr in patients with asymptomatic microscopic hematuria. Mild to moderate hypertension is most often seen in patients with nephritic or nephrotic syndrome, but is rarely severe enough to result in hypertensive emergencies. Normal serum levels of C3 in IgA nephropathy help to distinguish this disorder from post-streptococcal glomerulonephritis. Serum IgA levels have no diagnostic value because they are elevated in only 15% of pediatric patients.

PROGNOSIS AND TREATMENT

Although IgA nephropathy does not lead to significant kidney damage in most children, progressive disease develops in 20-30% of patients 15-20 yr after disease onset. Therefore, most children with IgA nephropathy do not display progressive renal dysfunction until adulthood, prompting the need for careful long-term follow-up. Poor prognostic indicators at presentation or follow-up include persistent hypertension, diminished renal function, and significant, increasing, or prolonged proteinuria. A more severe prognosis is correlated with histologic evidence of diffuse mesangial proliferation, extensive glomerular crescents, glomerulosclerosis, and diffuse tubulointerstitial changes, including inflammation and fibrosis.

The primary treatment of IgA nephropathy is appropriate blood pressure control and management of significant proteinuria. Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists are effective in reducing proteinuria and retarding the rate of disease progression when used individually or in combination. Fish oil, which contains antiinflammatory omega-3 polyunsaturated fatty acids, may decrease the rate of disease progression in adults. If renin-angiotensin blockade proves ineffective and significant proteinuria persists, then addition of immunosuppressive therapy with corticosteroids is recommended. Corticosteroids reduce proteinuria and improve renal function in those patients with a glomerular filtration rate >60 mL/min/m^2. It remains unclear if the effects of glucocorticoids deter progression to end-stage renal failure to a degree to offset their significant side effects. To date, additional immunosuppression with cyclophosphamide or azathioprine has not appeared to be effective, but further randomized clinical trials are in progress. Tonsillectomy has been used as treatment for IgA nephropathy in many countries including Japan. Performing a tonsillectomy in the absence of significant tonsillitis in association with IgA nephropathy is currently not recommended until appropriate prospective, controlled trials have been performed and demonstrate efficacy. Patients with IgA nephropathy may undergo successful kidney transplantation. Although recurrent disease is frequent, allograft loss caused by IgA nephropathy occurs in only 15-30% of patients.

510.2 Alport Syndrome

Cynthia G. Pan and Ellis D. Avner

AS, or hereditary nephritis, is a genetically heterogeneous disease caused by mutations in the genes coding for type IV collagen, a major component of basement membranes. These genetic alterations are associated with marked variability in clinical presentation, natural history, and histologic abnormalities.

GENETICS

Approximately 85% of patients have X-linked inheritance caused by a mutation in the *COL4A5* gene encoding the α5 chain of type IV collagen. Patients with a subtype of X-linked AS and diffuse leiomyomatosis demonstrate a contiguous mutation within the *COL4A5* and *COL4A6* genes that encodes the α5 and α6 chains, respectively, of type IV collagen. Autosomal recessive forms of AS are caused by mutations in the *COL4A3* and *COL4A4* genes on chromosome 2 encoding the α3 and α4 chains, respectively, of type IV collagen. An autosomal dominant form of AS linked to the *COL4A3-COL4A4* gene locus occurs in 5% of cases.

PATHOLOGY

Kidney biopsy specimens during the 1st decade of life show few changes on light microscopy. Later, the glomeruli may develop mesangial proliferation and capillary wall thickening, leading to progressive glomerular sclerosis. Tubular atrophy, interstitial inflammation and fibrosis, and lipid-containing tubular or interstitial cells, called *foam cells,* develop as the disease progresses. Immunopathologic studies are usually nondiagnostic.

In most patients, electron microscopy reveals diffuse thickening, thinning, splitting, and layering of the glomerular and tubular basement membranes (Fig. 510-3). To confound diagnosis, ultrastructural analysis of the GBM in all genetic forms of AS may be completely normal, display nonspecific alterations, or demonstrate only uniform thinning.

CLINICAL MANIFESTATIONS

All patients with AS have asymptomatic microscopic hematuria, which may be intermittent in girls and younger boys. Single or recurrent episodes of gross hematuria commonly occurring 1-2 days after an upper respiratory infection are seen in approximately 50% of patients. Proteinuria is often seen in boys but may be absent, mild, or intermittent in girls. Progressive proteinuria, often exceeding 1 g/24 hr, is common by the 2nd decade of life and can be severe enough to cause nephrotic syndrome.

Bilateral sensorineural hearing loss, which is never congenital, develops in 90% of hemizygous males with X-linked AS, 10% of heterozygous females with X-linked AS, and 67% of patients with autosomal recessive AS. This deficit begins in the high-frequency range, but progresses to involve hearing associated with normal speech, prompting the need for hearing aids. Ocular abnormalities, which occur in 30-40% of patients with X-linked AS, include anterior lenticonus (extrusion of the central portion of the lens into the anterior chamber), macular flecks, and corneal erosions. Leiomyomatosis of the esophagus, tracheobronchial tree, and female genitals in association with platelet abnormalities has been reported, but is rare.

DIAGNOSIS

A combination of careful family history, a screening urinalysis of 1st-degree relatives, an audiogram, and an ophthalmologic examination are critical in making the diagnosis of AS. The presence of anterior lenticonus is pathognomonic. AS is highly likely in the patient who has hematuria and at least 2 of the following characteristic clinical features: macular flecks, recurrent corneal erosions, GBM thickening and thinning, or sensorineural deafness. Absence of epidermal basement membrane staining for the α5 chain of type IV collagen in male hemizygotes and discontinuous epidermal basement membrane staining in female heterozygotes on skin biopsy is pathognomonic for X-linked AS and can preclude diagnostic renal biopsy. Genetic testing is clinically available for X-linked AS and *COL4A5* mutations. Prenatal diagnosis is available for families with members who have X-linked AS and who carry an identified mutation.

PROGNOSIS AND TREATMENT

The risk of progressive renal dysfunction leading to end-stage renal disease (ESRD) is highest among hemizygotes and autosomal recessive homozygotes. ESRD occurs before age 30 yr in approximately 75% of hemizygotes with X-linked AS. The risk of ESRD in X-linked heterozygotes is 12% by age 40 yr and 30% by age 60 yr. Risk factors for progression are gross hematuria during childhood, nephrotic syndrome, and prominent GBM thickening. Intrafamilial variation in phenotypic expression results in significant differences in the age of ESRD among family members. No specific therapy is available to treat AS, although angiotensin-converting enzyme inhibitors (and possibly angiotensin-2 receptor inhibitors) can slow the rate of progression. Careful management of renal failure complications such as hypertension, anemia, and electrolyte imbalance is critical. Patients with ESRD are treated with dialysis and kidney transplantation (see Chapter 535). Approximately 5% of kidney transplantation recipients develop anti-GBM nephritis, which occurs primarily in males with X-linked AS who develop ESRD before age 30 yr.

Pharmacologic treatment of proteinuria with angiotensin-converting enzyme inhibition or angiotensin II receptor blockade has proven effective in other glomerular diseases and has also shown promise in AS. Screening of heterozygote carriers for significant renal disease in later adulthood and possible treatment of significant proteinuria is also recommended.

Bibliography is available at Expert Consult.

510.3 Thin Basement Membrane Disease

Cynthia G. Pan and Ellis D. Avner

Thin basement membrane disease (TBMD) is defined by the presence of persistent microscopic hematuria and isolated thinning of the GBM (and, occasionally, tubular basement membranes) on electron microscopy. Microscopic hematuria is often initially observed during childhood and may be intermittent. Episodic gross hematuria can also be present, particularly after a respiratory illness. Isolated hematuria in multiple family members without renal dysfunction is referred to as **benign familial hematuria**. Although most of these patients will not undergo renal biopsy, it is often presumed that the underlying pathology is TBMD. TBMD may be sporadic or transmitted as an autosomal dominant trait. Heterozygous mutations in the *COL4A3* and *COL4A4* genes, which encode the α3 and α4 chains of type IV collagen present in the GBM, result in TBMD. Rare cases of TBMD progress, and such patients develop significant proteinuria, hypertension, or renal insufficiency. Homozygous mutations in these same genes result in autosomal recessive AS. Therefore, in these rare cases, the absence of a positive family history for renal insufficiency or deafness would not necessarily predict a benign outcome. Consequently, monitoring patients with benign familial hematuria for progressive proteinuria, hypertension, or renal insufficiency is important through childhood and young adulthood.

Chapter 511

Glomerulonephritis Associated with Infections

511.1 Acute Poststreptococcal Glomerulonephritis

Cynthia G. Pan and Ellis D. Avner

Group A β-hemolytic streptococcal infections are common in children and can lead to the postinfectious complication of acute glomerulonephritis (GN). Acute poststreptococcal glomerulonephritis (APSGN) is a classic example of the **acute nephritic syndrome** characterized by the sudden onset of gross hematuria, edema, hypertension, and renal insufficiency. It is one of the most common glomerular causes of gross

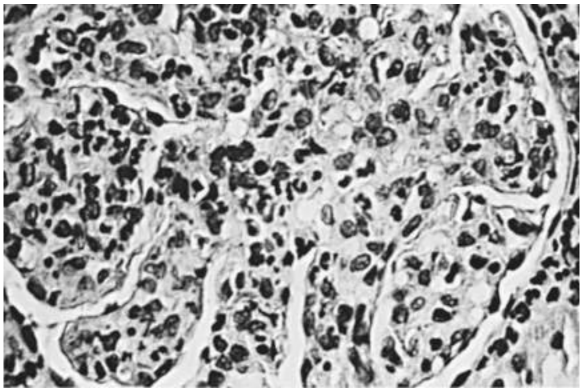

Figure 511-1 Glomerulus from a patient with poststreptococcal glomerulonephritis appears enlarged and relatively bloodless and shows mesangial proliferation and exudation of neutrophils (×400).

hematuria in children and is a major cause of morbidity in group A β-hemolytic streptococcal infections.

ETIOLOGY AND EPIDEMIOLOGY

APSGN follows infection of the throat or skin by certain "nephritogenic" strains of group A β-hemolytic streptococci. Epidemics and clusters of household (camps, military) cases occur throughout the world, and 97% of cases occur in less-developed countries. The overall incidence has decreased in industrialized nations, presumably as a result of improved hygienic conditions and the near eradication of streptococcal pyoderma. Poststreptococcal GN commonly follows streptococcal pharyngitis during cold-weather months and streptococcal skin infections or pyoderma during warm-weather months. Although epidemics of nephritis have been described in association with throat (serotypes M1, M4, M25, and some strains of M12) and skin (serotype M49) infections, this disease is most commonly sporadic.

PATHOLOGY

Glomeruli appear enlarged and relatively bloodless and show diffuse mesangial cell proliferation, with an increase in mesangial matrix (Fig. 511-1). Polymorphonuclear leukocyte infiltration is common in glomeruli during the early stage of the disease. Crescents and interstitial inflammation may be seen in severe cases, but these changes are not specific for poststreptococcal GN. Immunofluorescence microscopy reveals a pattern of "lumpy-bumpy" deposits of immunoglobulin and complement on the glomerular basement membrane and in the mesangium. On electron microscopy, electron-dense deposits, or "humps," are observed on the epithelial side of the glomerular basement membrane (Fig. 511-2).

PATHOGENESIS

Morphologic studies and a depression in the serum complement (C3) level provide strong evidence that ASPGN is mediated by immune complexes. Circulating immune complex formation with streptococcal antigens and subsequent glomerular deposition is thought less likely to be a pathogenic mechanism. Molecular mimicry whereby circulating antibodies elicited by streptococcal antigens react with normal glomerular antigens, in situ immune complex formation of antistreptococcal antibodies with glomerular deposited antigen, and complement activation by directly deposited streptococcal antigens continue to be considered as probable mechanisms of immunologic injury.

Group A streptococci possess M proteins, and nephritogenic strains are related to the M protein serotype. The search for the precise nephritogenic antigen(s) that cause disease suggests that streptococcal pyogenic exotoxin (SPE) B and nephritis-associated streptococcal plasmin receptor are promising candidates. Both have been identified in glomeruli of affected patients, and in 1 study, circulating antibodies to SPE B were found in all patients. Cross-reactivity of SPE B and other M proteins with various components of the glomerular basement membrane also give evidence for molecular mimicry.

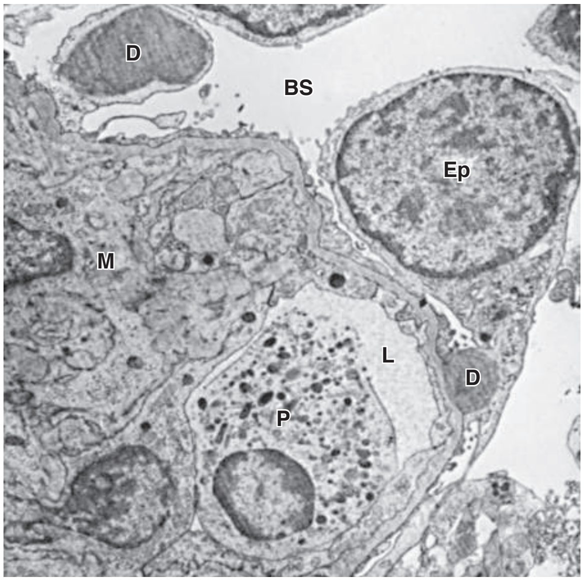

Figure 511-2 **Electron micrograph in poststreptococcal glomerulonephritis demonstrating electron-dense deposits (D) on the epithelial cell (Ep) side of the glomerular basement membrane.** A polymorphonuclear leukocyte (P) is present within the lumen (L) of the capillary. BS, Bowman space; M, mesangium.

CLINICAL MANIFESTATIONS

Poststreptococcal GN is most common in children ages 5-12 yr and uncommon before the age of 3 yr. The typical patient develops an acute nephritic syndrome 1-2 wk after an antecedent streptococcal pharyngitis or 3-6 wk after a streptococcal pyoderma. The history of a specific infection may be absent, because symptoms may have been mild or have resolved without patients receiving specific treatment or seeking the care of a medical provider.

The severity of kidney involvement varies from asymptomatic microscopic hematuria with normal renal function to gross hematuria with acute renal failure. Depending on the severity of renal involvement, patients can develop various degrees of edema, hypertension, and oliguria. Patients are at risk for developing encephalopathy and/or heart failure secondary to hypertension or hypervolemia. Hypertensive encephalopathy must be considered in patients with blurred vision, severe headaches, altered mental status, or new seizures. The effects of acute hypertension not only depend on the severity of hypertension but also the absolute change in comparison to the patient's baseline blood pressure and the rate at which it has risen. Respiratory distress, orthopnea, and cough may be symptoms of pulmonary edema and heart failure. Peripheral edema typically results from salt and water retention and is common; nephrotic syndrome develops in a minority (<5%) of childhood cases. Nonspecific symptoms such as malaise, lethargy, abdominal pain, or flank pain are common. Atypical presentations of APSGN include those with subclinical disease and those with severe symptoms but an absence of initial urinary abnormalities; in individuals who present with a purpuric rash, it is difficult to distinguish APSGN from Henoch-Schönlein purpura without a renal biopsy.

The acute phase generally resolves within 6-8 wk. Although urinary protein excretion and hypertension usually normalize by 4-6 wk after onset, persistent microscopic hematuria can persist for 1-2 yr after the initial presentation.

DIAGNOSIS

Urinalysis demonstrates red blood cells, often in association with red blood cell casts, proteinuria, and polymorphonuclear leukocytes. A

mild normochromic anemia may be present from hemodilution and low-grade hemolysis. The serum C3 level is significantly reduced in >90% of patients in the acute phase, and returns to normal 6-8 wk after onset. Although serum CH_{50} is commonly depressed, C4 is most often normal in APSGN, or only mildly depressed.

Confirmation of the diagnosis requires clear evidence of a prior streptococcal infection. A positive throat culture report might support the diagnosis or might represent the carrier state. A rising antibody titer to streptococcal antigen(s) confirms a recent streptococcal infection. The antistreptolysin O titer is commonly elevated after a pharyngeal infection but rarely increases after streptococcal skin infections. The best single antibody titer to document cutaneous streptococcal infection is the antideoxyribonuclease B level. If available, a positive streptozyme screen (which measures multiple antibodies to different streptococcal antigens) is a valuable diagnostic tool. Serologic evidence for streptococcal infections is more sensitive than the history of recent infections and far more sensitive than positive bacterial cultures obtained at the time of onset of acute nephritis.

Magnetic resonance imaging of the brain is indicated in patients with severe neurologic symptoms and can demonstrate **posterior reversible encephalopathy syndrome** in the parietooccipital areas on T2-weighted images. Chest x-ray is indicated in those with signs of heart failure or respiratory distress, or physical exam findings of a heart gallop, decreased breath sounds, rales, or hypoxemia.

The clinical diagnosis of poststreptococcal GN is quite likely in a child presenting with acute nephritic syndrome, evidence of recent streptococcal infection, and a low C3 level. However, it is important to consider other diagnoses such as systemic lupus erythematosus, endocarditis, membranoproliferative GN, and an acute exacerbation of chronic GN. Renal biopsy should be considered only in the presence of acute renal failure, nephrotic syndrome, absence of evidence of streptococcal infection, or normal complement levels. In addition, renal biopsy is considered when hematuria and proteinuria, diminished renal function, and/or a low C3 level persist more than 2 mo after onset. Persistent hypocomplementemia can indicate a chronic form of postinfectious GN or another disease such as membranoproliferative GN.

The differential diagnosis of poststreptococcal GN includes many of the causes of hematuria listed in Tables 509-2 and 511-1, and an algorithm to help with diagnosis is presented in Figure 511-3. Acute postinfectious GN can also follow other infections with coagulase-positive and coagulase-negative staphylococci, *Streptococcus pneumoniae,* and Gram-negative bacteria. The clinical course, histopathology, and laboratory features are similar to those described for APSGN. For some, the terms APSGN and acute postinfectious GN are used synonymously. Acute GN can occur after certain fungal, rickettsial, protozoan, parasitic, or viral diseases. Among the latter, influenza and parvovirus infections are particularly notable.

COMPLICATIONS

Acute complications result from hypertension and acute renal dysfunction. Hypertension is seen in 60% of patients and is associated

Table 511-1 Summary of Primary Renal Diseases That Manifest as Acute Glomerulonephritis

DISEASES	POSTSTREPTOCOCCAL GLOMERULONEPHRITIS	IgA NEPHROPATHY	GOODPASTURE SYNDROME	IDIOPATHIC RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS
CLINICAL MANIFESTATIONS				
Age and sex	All ages, mean 7 yr, 2:1 male	10-35 yr, 2:1 male	15-30 yr, 6:1 male	Adults, 2:1 male
Acute nephritic syndrome	90%	50%	90%	90%
Asymptomatic hematuria	Occasionally	50%	Rare	Rare
Nephrotic syndrome	10-20%	Rare	Rare	10-20%
Hypertension	70%	30-50%	Rare	25%
Acute renal failure	50% (transient)	Very rare	50%	60%
Other	Latent period of 1-3 wk	Follows viral syndromes	Pulmonary hemorrhage; iron deficiency anemia	None
Laboratory findings	↑ ASO titers (70%) Positive streptozyme (95%) ↓C3-C9; normal C1, C4	↑ Serum IgA (50%) IgA in dermal capillaries	Positive anti-GBM antibody	Positive ANCA in some
Immunogenetics	HLA-B12, D "EN" (9)*	HLA-Bw 35, DR4 (4)*	HLA-DR2 (16)*	None established
RENAL PATHOLOGY				
Light microscopy	Diffuse proliferation	Focal proliferation	Focal → diffuse proliferation with crescents	Crescentic GN
Immunofluorescence	Granular IgG, C3	Diffuse mesangial IgA	Linear IgG, C3	No immune deposits
Electron microscopy	Subepithelial humps	Mesangial deposits	No deposits	No deposits
Prognosis	95% resolve spontaneously 5% RPGN or slowly progressive	Slow progression in 25-50%	75% stabilize or improve if treated early	75% stabilize or improve if treated early
Treatment	Supportive	Uncertain (options include steroids, fish oil, and ACE inhibitors)	Plasma exchange, steroids, cyclophosphamide	Steroid pulse therapy

with hypertensive encephalopathy in 10% of cases. Although the neurologic sequelae are often reversible with appropriate management, severe prolonged hypertension can lead to intracranial bleeding. Other potential complications include heart failure, hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, seizures, and uremia. Acute renal failure can require treatment with dialysis.

PREVENTION

Early systemic antibiotic therapy for streptococcal throat and skin infections does not eliminate the risk of GN. Family members of patients with acute GN, especially young children, should be considered at risk and be cultured for group A β-hemolytic streptococci and treated if positive. Family pets, particularly dogs, have also been reported as carriers.

TREATMENT

Management is directed at treating the acute effects of renal insufficiency and hypertension (see Chapter 535.1). Although a 10 day course of systemic antibiotic therapy with penicillin is recommended to limit the spread of the nephritogenic organisms, antibiotic therapy does not affect the natural history of APSGN. This is unlike the GN seen in the context of ongoing or chronic infections, as noted in Chapter 511.2. Sodium restriction, diuresis (usually with intravenous furosemide), and pharmacotherapy with calcium channel antagonists, vasodilators, or angiotensin-converting enzyme inhibitors, are standard therapies used to treat hypertension.

PROGNOSIS

Complete recovery occurs in >95% of children with APSGN. Recurrences are extremely rare. Mortality in the acute stage can be avoided by appropriate management of acute renal failure, cardiac failure, and hypertension. Infrequently, the acute phase is severe and leads to glomerulosclerosis and chronic renal disease in <2% of affected children.

Bibliography is available at Expert Consult.

511.2 Other Chronic Infections

Cynthia G. Pan and Ellis D. Avner

GN is a recognized complication of various chronic infections. Classic examples include bacterial endocarditis caused by viridans streptococcus and other organisms, and ventriculoatrial shunts infected with *Staphylococcus epidermidis.* Other infections, observed less commonly in children than in adults, include hepatitis B virus, hepatitis C virus, syphilis, and candidiasis. Parasitic infections associated with glomerular disease include malaria, schistosomiasis, leishmaniasis, filariasis, hydatid disease, trypanosomiasis, and toxoplasmosis. In each condition, the infecting organism has low virulence and the host is chronically infected with foreign antigen. In the presence of high levels of circulating antigen, the host's antibody response leads to formation of immune complexes that deposit in the kidneys and initiate glomerular inflammation. Foreign antigens can also stimulate an autoimmune response through the production of antibodies that cross-react with such antigens incorrectly "recognized" as glomerular structural components.

The renal histopathology can resemble poststreptococcal GN, membranous GN, or membranoproliferative GN. The clinical manifestations are generally those of an acute nephritic or nephrotic syndrome. The serum C3 and CH_{50} complement levels are often decreased.

In HIV-associated nephropathy, direct viral infection of nephrons occurs because renal cells express a variety of lymphocyte chemokine receptors that are essential for and facilitate viral invasion. The renal expression of HIV infection is quite variable and includes an immune complex injury and a direct cytopathic effect. The classic histopathologic lesion of HIV-associated nephropathy is focal segmental glomerulosclerosis, but systemic lupus erythematosus–like glomerulonephritis, immunoglobulin A nephropathy, and membranous nephropathy have been reported. In the era of antiretroviral therapy, the decline in mortality has led to the increased recognition of renal disorders as an important complication to perinatally HIV-infected children.

Prompt eradication of any infection before severe glomerular injury occurs usually results in resolution of the GN. Progression to end-stage renal failure has been described but is uncommon. Spontaneous resolution of hepatitis B infection is common in children (30-50%) and results in remission of the glomerulopathy. Specific antivirals, interferon therapy, plasmapheresis, and immunosuppressive treatment have all been used successfully in adults with hepatitis C disease, but no controlled trials with any of these agents have been performed in pediatric patients.

Chapter 512
Membranous Nephropathy

Scott K. Van Why and Ellis D. Avner

Membranous nephropathy (MN), amongst the most common causes of nephrotic syndrome in adults, is a rare cause of nephrotic syndrome in children. MN is classified as the primary, idiopathic form, where there is isolated renal disease, or secondary MN, where nephropathy is associated with other identifiable systemic diseases or medications. In children, secondary MN is far more common than primary, idiopathic MN. The most common etiologies of secondary MN are systemic lupus erythematosus or chronic infections. Among the latter, chronic hepatitis B infection and congenital syphilis are the best characterized and recognized causes of MN. Other chronic infections have also been associated with MN, including malaria, which is likely the most common cause of nephrotic syndrome worldwide. Certain medications, such as penicillamine and gold, or chronic factor replacement in patients with hemophilia can also cause MN. Rare causes associated with MN include tumors, such as neuroblastoma, or other idiopathic systemic diseases. Identification of secondary causes of MN is critical, because removal of the offending agent or treatment of the causative disease often leads to resolution of the associated nephropathy and improves patient outcome.

PATHOLOGY

Glomeruli have diffuse thickening of the glomerular basement membrane (GBM), without significant cell proliferative changes. Immunofluorescence and electron microscopy typically demonstrate granular deposits of immunoglobulin G and C3 located on the epithelial side of the GBM. The GBM thickening presumably results from the production of membrane-like material in response to deposition of immune complexes.

PATHOGENESIS

MN is believed to be caused by in situ immune complex formation. Therefore, antigens from the infectious agents or medications associated with secondary MN directly contribute to the pathogenesis of the renal disease. The causative antigen in idiopathic MN is not established, but the M-type phospholipase A_2 receptor, present on normal podocytes, may be a target antigen in idiopathic MN. Antigen from this receptor is found in immune deposits extracted from glomeruli in patients with idiopathic MN. The majority of idiopathic MN patients have circulating antibody against this podocyte membrane antigen, as well as against several podocyte cytoplasmic antigens. Childhood MN may be associated with anticationic bovine serum albumin antibodies. In addition, neutral endopeptidase antigen may be the antigen in neonatal onset MN.

CLINICAL MANIFESTATIONS

In children, MN is most common in the 2nd decade of life, but it can occur at any age, including infancy. The disease usually manifests as nephrotic syndrome and accounts for 2-6% of all cases of childhood nephrotic syndrome. Most patients also have microscopic hematuria and only rarely present with gross hematuria. Approximately 20% of children have hypertension at presentation. A subset of patients with MN present with a major venous thrombosis, commonly renal vein thrombosis. This well-known complication of nephrotic syndrome (see Chapter 527) is particularly common in patients with MN. Serum C3 and CH_{50} levels are normal, except in cases of systemic lupus erythematosus, where levels may be depressed (see Fig. 511-3 in Chapter 511).

DIAGNOSIS

MN might be suspected on clinical grounds, particularly in the setting of known risk factors for secondary forms of the disease. The diagnosis can only be established by renal biopsy. No serologic test is specific for MN, but finding an active carrier state for hepatitis B or congenital syphilis would make the diagnosis probable in the appropriate clinical setting. Common indications for renal biopsy leading to the diagnosis of MN include presentation with nephrotic syndrome in a child >10 yr or unexplained persistent hematuria with significant proteinuria.

PROGNOSIS AND TREATMENT

The clinical course of idiopathic membranous glomerulopathy is variable. Children presenting with asymptomatic, low-grade proteinuria can enter remission spontaneously. Retrospective reports of children 1-15 yr after diagnosis, treated with a variety of regimens, indicate that 20% progress to chronic renal failure, 40% continue with active disease, and 40% achieve complete remission. Although no controlled trials have been performed in children, immunosuppressive therapy with an extended course of prednisone can be effective in promoting complete resolution of symptoms. The addition of chlorambucil or cyclophosphamide appears to provide further benefit to those not responding to steroids alone. Rituximab has shown significant promise in adults and has been proposed by some as first line treatment but has yet to be studied in a randomized controlled trial in any age group. For those unresponsive to immunosuppression, or with mild clinical features, proteinuria can be reduced with angiotensin-converting enzyme inhibitors, and by analogy, probably angiotensin-II–receptor blockers.

Chapter 513

Membranoproliferative Glomerulonephritis

Scott K. Van Why and Ellis D. Avner

Membranoproliferative glomerulonephritis (MPGN), also known as mesangiocapillary glomerulonephritis, most commonly occurs in children or young adults. MPGN can be classified into primary (idiopathic) and secondary forms of glomerular disease. Secondary forms of MPGN are most commonly associated with subacute and chronic infection, including hepatitides B and C, syphilis, subacute bacterial endocarditis, and infected shunts, especially ventriculoatrial shunts (shunt nephritis). MPGN can also be one of the glomerular lesions seen in lupus nephritis (see Chapter 514).

PATHOLOGY

Primary MPGN is defined by the histologic pattern of glomeruli as seen by light, immunofluorescence, and electron microscopy. Two subtypes have been defined on histologic criteria and are associated with different clinical phenotypes. **Type I MPGN** is most common. Glomeruli have an accentuated lobular pattern from diffuse mesangial expansion, endocapillary proliferation, and an increase in mesangial cells and matrix. The glomerular capillary walls are thickened, often with splitting from interposition of the mesangium. Crescents, if present, indicate a poor prognosis. Immunofluorescence microscopy reveals C3 and lesser amounts of immunoglobulin in the mesangium and along the peripheral capillary walls in a lobular pattern. Electron

microscopy confirms numerous deposits in the mesangial and subendothelial regions.

Far less common is **type II MPGN,** also called dense deposit disease, which has similar light microscopic findings as type I MPGN. Differentiation from type I disease is by immunofluorescence and electron microscopy. In type II disease, C3 immunofluorescence typically is prominent, without concomitant immunoglobulin. By electron microscopy, the lamina densa in the glomerular basement membrane undergoes a very dense transformation, without evident immune complex–type deposits.

C3 glomerulonephritis (C3GN) is a related but separate diagnostic category. By light and electron microscopy C3GN usually has features indistinguishable from classical MPGN. Immunofluorescence studies distinguish between the two, with C3GN having only C3 deposition and MPGN having both C3 and immunoglobulin fluorescence.

PATHOGENESIS

Although the histology of **type I MPGN** produced by primary and secondary forms is indistinguishable, it appears that **type I** disease occurs when circulating immune complexes become trapped in the glomerular subendothelial space, which then causes injury, resulting in the characteristic proliferative response and mesangial expansion. Further evidence confirming this pathway to glomerular injury is the finding of complement activation through the classical pathway in as many as 50% of affected patients.

Type II MPGN appears **not** to be mediated by immune complexes. The pathogenesis of the disease is not known, but the characteristic finding of severely depressed serum complement levels suggests that deranged complement regulation might play a major role in the disease. A typical finding is markedly depressed serum C3 complement levels, with normal levels of other complement components. In many patients with type II MPGN, **C3 nephritic factor** (anti–C3 convertase antibody) is present. This factor activates the alternative complement pathway. In unusual cases, patients with type II MPGN demonstrate an associated systemic disease called **partial lipodystrophy**, where there is diffuse loss of adipose tissue and decreased complement in the presence of C3 nephritic factor. Correlation between the presence of C3 nephritic factor, complement levels, and disease presence or severity is not strong, indicating that the complement abnormalities alone are not sufficient to cause the disease.

Type II MPGN (dense deposit disease) is considered part of the broader spectrum of C3GN. The latter, as defined above pathologically, appears to be caused by primary dysregulation of the alternative or terminal cascade complement pathways.

CLINICAL MANIFESTATIONS

MPGN is most common in the 2nd decade of life. Systemic features may provide clues to which type of MPGN may be present, but the two histologic types of idiopathic MPGN are indistinguishable in terms of their renal manifestations. Patients present in equal proportions with nephrotic syndrome, acute nephritic syndrome (hematuria, hypertension, and some level of renal insufficiency), or persistent asymptomatic microscopic hematuria and proteinuria. Serum C3 complement levels are low in the majority of cases (see Fig. 511-3 in Chapter 511).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes all forms of acute and chronic glomerulonephritis, including idiopathic and secondary forms, along with postinfectious glomerulonephritis. Postinfectious glomerulonephritis, far more common than MPGN, usually does not have nephrotic features but typically has hematuria, hypertension, renal insufficiency, and transiently low C3 complement, all features that may be seen with MPGN or C3GN. In contrast to MPGN and C3GN, where C3 levels usually remain persistently low, C3 returns to normal within 2 mo after onset of postinfectious glomerulonephritis (see Chapter 511.3). The diagnosis of MPGN is made by renal biopsy. Indications for biopsy include nephrotic syndrome in an older child, significant proteinuria with microscopic hematuria, and hypocomplementemia lasting >2 mo in a child with acute nephritis. If C3 but no immunoglobulin deposition is found in glomeruli with MPGN, genetic testing and functional assays to define defects of complement cascade regulation should be pursued.

PROGNOSIS AND TREATMENT

It is important to determine whether MPGN is idiopathic or secondary to a systemic disease, particularly lupus or chronic infection, because treatment of the causative disease can result in resolution of MPGN. Untreated, idiopathic MPGN, regardless of type, has a poor prognosis. By 10 yr following onset, 50% of patients with MPGN have progressed to end-stage renal disease. By 20 yr following onset, up to 90% have lost renal function. Those with nephrotic syndrome at the time of presentation progress to renal failure more rapidly. No definitive therapy exists, but several reports, including a randomized controlled trial, indicate that extended courses of alternate-day prednisone (for years) provide benefit. Some patients treated with steroids enter a complete clinical remission of their disease, but many have ongoing disease activity. Nevertheless, an extended course of prednisone is associated with significant preservation of renal function when compared with patients receiving no such treatment.

The prognosis of C3GN, separate from dense deposit disease (considered a part of C3GN by some) and other forms of classically defined MPGN is as yet hard to define, since reports of outcome of such patients previously had been grouped in studies of all forms of MPGN (types I and II, and even a poorly characterized type III form not considered above). The apparent pathophysiology of C3GN promises that treatments targeting the interruption of complement activation pathways, such as complement factor H replacement or shutting down the terminal complement cascade by blocking C5 activation with eculizumab (anti–C5 antibody), could be beneficial in preventing progression of renal disease.

Chapter 514

Glomerulonephritis Associated with Systemic Lupus Erythematosus

Cynthia G. Pan and Ellis D. Avner

Systemic lupus erythematosus (SLE) is characterized by fever, weight loss, dermatitis, hematologic abnormalities, arthritis, and involvement of the heart, lungs, central nervous system, and kidneys (see Chapter 158). Glomerulonephritis is the most important cause of morbidity and mortality in SLE. Renal disease in childhood SLE is present in up to 80% of patients and is more active than that seen in adults. Occasionally, renal disease is the only presenting clinical manifestation.

PATHOGENESIS AND PATHOLOGY

The clinical manifestations of SLE are mediated by immune complexes. Autoantibodies are directed predominantly at nuclear antigens which act as immunogens. Binding of autoantibodies to glomerular components rather than the passive "trapping" of circulating immune complexes is central to the development of glomerulonephritis. Other pathogenic mechanisms include alterations in innate immunity that

result in amplification of inflammation. Deficiency of the complement component C1q is rare but is the strongest single genetic risk for SLE.

Kidney biopsy and evaluation of renal histopathology remain the gold standard for establishing the diagnosis of SLE nephritis and determining specific therapeutic regimens. The World Health Organization (WHO) classification of lupus nephritis is based on a combination of features including light microscopy, immunofluorescence, and electron microscopy. In patients with **WHO class I nephritis** (minimal mesangial lupus nephritis), no histologic abnormalities are detected on light microscopy but mesangial immune deposits are present on immunofluorescence or electron microscopy. In **WHO class II nephritis** (mesangial proliferative nephritis), light microscopy shows both mesangial hypercellularity and increased matrix along with mesangial deposits containing immunoglobulin and complement.

WHO class III nephritis and **WHO class IV nephritis** are interrelated lesions characterized by both mesangial and endocapillary lesions. Class III nephritis is defined by <50% glomeruli with involvement and class IV has ≥50% glomerular involvement. Immune deposits are present in both the mesangium and subendothelial areas. A subclassification scheme helps grade severity of the proliferative lesion based on whether the glomerular lesions are segmental (<50% glomerular tuft involved) or global (≥50% glomerular tuft involved). The WHO classification scheme also delineates whether there is a predominance of chronic disease versus active disease. Chronic injury results in glomerular sclerosis and is felt to be the consequence of significant proliferative disease seen in classes III and IV. Other signs of active disease include capillary walls that are thickened secondary to subendothelial deposits (creating the wire-loop lesion), necrosis, and crescent formation. WHO class IV nephritis is associated with poorer outcomes but can be successfully treated with aggressive immunosuppressive therapy.

WHO class V nephritis (membranous lupus nephritis) is less commonly seen as an isolated lesion and resembles idiopathic membranous nephropathy with subepithelial immune deposits. This lesion is often seen in combination with class III or IV proliferative nephritis, and if the membranous lesion is present in >50% glomeruli, both classes are noted in designation. This classification scheme also identifies cases with combinations of mixed classes III, IV, and V lesions, directing appropriate treatment for such patients. Another classification scheme by both the International Society of Nephrology and the Renal Pathology Society differs mainly in its subclassification of class IV into diffuse global and diffuse segmental lesions (Table 514-1). The value of utilizing this classification scheme, and more importantly, its impact on therapy and the results of clinical trials is unknown at this time.

Transformation of the histologic lesions of lupus nephritis from one class to another is common. This is more likely to occur among inadequately treated patients and usually results in progression to a more severe histologic lesion.

Table 514-1 Classification of Lupus Nephritis

CLASS	CLINICAL FEATURES
I. Minimal mesangial LN	No renal findings
II. Mesangial proliferative LN	Mild clinical renal disease; minimally active urinary sediment; mild to moderate proteinuria (never nephrotic) but may have active serology
III. Focal proliferative LN <50% glomeruli involved A. Active A/C. Active and chronic C. Chronic	More active sediment changes; often active serology; increased proteinuria (approximately 25% nephrotic); hypertension may be present; some evolve into class IV pattern; active lesions require treatment, chronic do not
IV. Diffuse proliferative LN (>50% glomeruli involved); all may be with segmental or global involvement (S or G) A. Active A/C. Active and chronic C. Chronic	Most severe renal involvement with active sediment, hypertension, heavy proteinuria (frequent nephrotic syndrome), often reduced glomerular filtration rate; serology very active. Active lesions require treatment
V. Membranous LN glomerulonephritis	Significant proteinuria (often nephrotic) with less active lupus serology
VI. Advanced sclerosing LN	More than 90% glomerulosclerosis; no treatment prevents renal failure

LN, lupus nephritis.

From Appel GB, Radhakrishnan J: Glomerular disorders and nephrotic syndromes. In Goldman L, Schafer AI, editors, Goldman's Cecil medicine, *ed 24, St. Louis, 2012, Elsevier Saunders, Table 123-7, p. 769.*

CLINICAL MANIFESTATIONS

The majority of children with SLE are adolescent females. Lupus nephritis affects most pediatric patients, and although commonly presenting within the first year of diagnosis, may occur at any time during the course of the disease. Ethnicity and socioeconomic factors strongly predict the development of lupus nephritis in adults with SLE but not in children. The clinical findings in patients having milder forms of lupus nephritis (all classes I-II, some class III) include hematuria, normal renal function, and proteinuria <1 g/24 hr. Some patients with class III and all patients with class IV nephritis have hematuria and proteinuria, hypertension, reduced renal function, nephrotic syndrome, or acute renal failure. The urinalysis may be normal on rare occasions in patients with proliferative lupus nephritis. Patients with class V nephritis commonly present with nephrotic syndrome.

DIAGNOSIS

The diagnosis of SLE is confirmed by the detection of circulating antinuclear antibodies and by demonstrating antibodies that react with native double-stranded DNA. In most patients with active disease, C3 and C4 levels are depressed. In view of the lack of a clear correlation between the clinical manifestations and the severity of the renal involvement, renal biopsy should be performed in all patients with SLE. Histopathologic findings are used to determine the selection of specific immunosuppressive therapies.

TREATMENT

Children with SLE should be treated by pediatric specialists in medical centers where medical and psychologic support can be provided for patients and their families. The goal of immunosuppressive therapy in lupus nephritis is to produce both a clinical remission, defined as normalization of renal function and proteinuria, and a serologic remission, defined as normalization of anti-DNA antibody, C3, and C4 levels. Therapy is initiated in all patients with prednisone at a dose of 1-2 mg/kg/day in divided doses followed by a slow steroid taper over 4-6 mo beginning 4-6 wk after achieving a serologic remission. For patients with severe forms of nephritis (WHO classes III and IV), induction therapy consists of 6 consecutive monthly intravenous infusions of cyclophosphamide at a dose of 500-1,000 mg/m^2. Pulse intravenous methylprednisolone (1000 mg/m^2) is also used in addition to oral corticosteroids. In adult clinical trials, mycophenolate mofetil was shown to be equally efficacious for induction therapy and may be considered for use in children using 600 mg/m^2 per dose twice daily. Maintenance therapy previously consisted of additional Cytoxan infusions every 3 mo for 18 mo, which reduced the risk of progressive renal dysfunction. Maintenance therapy using mycophenolate mofetil or azathioprine may be as efficacious as intravenous cyclophosphamide and result in less-serious side effects, such as infections, hair loss, hemorrhagic cystitis, and gonadal failure. Mycophenolate mofetil is particularly more efficacious than cyclophosphamide in African-Americans. Azathioprine, at a single daily dose of 1.5-2.0 mg/kg, may be used as a steroid-sparing agent in patients with WHO class I or II

lupus nephritis. Rituximab, a chimeric monoclonal antibody specific for human CD20, is ineffective for induction therapy for diffuse proliferative disease but may be considered in cases where resistance to conventional treatment is demonstrated. Plasmapheresis is ineffective in lupus nephritis unless there is accompanying thrombotic thrombocytopenic purpura or antineutrophilic cytoplasmic antibody–associated disease. New therapies include belimumab, a fully humanized monoclonal antibody against a type II transmembrane protein that functions in the normal survival and differentiation of B cells, which is FDA-approved for use in SLE. Its role in lupus nephritis, either in combination with current therapies or to replace them, requires extensive further study.

Hydrochloroquine is prescribed in most patients with SLE for extrarenal manifestations, but is thought to have a beneficial effect in maintaining remission in lupus nephritis. It is a rational choice given its low side effect profile. Use of antihypertensive drugs to aggressively treat hypertension as well as the specific use of drugs that block the renin–angiotensin system (angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers) to reduce proteinuria are also important therapies that appear to decrease long-term progression of renal disease.

PROGNOSIS

Overall, renal survival (defined as chronic kidney disease without the need for end-stage renal disease therapy) is seen in 80% of patients 10 yr after the diagnosis of SLE nephritis. Patients with diffuse proliferative WHO class IV lupus nephritis exhibit the highest risk for progression to end-stage renal disease. Concerns regarding the side effects of chronic immunosuppressive therapy and the risk of recurrent disease are lifelong. Close monitoring for relapse of disease is critical to ensure maximally successful renal outcomes. Special care must be taken to minimize the risks of infection, osteoporosis, obesity, poor growth, hypertension, and diabetes mellitus associated with chronic corticosteroid therapy. Patients require counseling regarding the risk of malignancy or infertility, which may be increased in those receiving a cumulative dose of >20 g of cyclophosphamide or other immunosuppressant therapies.

Chapter 515

Henoch-Schönlein Purpura Nephritis

Scott K. Van Why and Ellis D. Avner

Henoch-Schönlein purpura (HSP) is the most common small vessel vasculitis in childhood. It is characterized by a purpuric rash and commonly accompanied by arthritis and abdominal pain (see Chapter 167.1). Approximately 50% of patients with HSP develop renal manifestations, which vary from asymptomatic microscopic hematuria to severe, progressive glomerulonephritis.

PATHOGENESIS AND PATHOLOGY

The pathogenesis of HSP nephritis appears to be mediated by the deposition of polymeric immunoglobulin A (IgA) in glomeruli. This is analogous to the same type of IgA deposits seen in systemic small vessels, primarily those of the skin and intestine. The glomerular findings can be indistinguishable from those of IgA nephropathy (see Chapter 510.1). IgA deposits are present by immunofluorescence, and a broad spectrum of glomerular lesions that can range from mild proliferation to necrotic and crescentic changes can be seen.

CLINICAL AND LABORATORY MANIFESTATIONS

The nephritis associated with HSP usually follows onset of the rash, often presenting weeks or even months after the initial presentation of the disease. Nephritis can be manifest at initial presentation, but only rarely before onset of the rash. Patients at presentation rarely display a severe combined acute nephritic and nephrotic picture (hematuria, hypertension, renal insufficiency, significant proteinuria, and nephrotic syndrome). Most patients have only mild renal manifestations, principally isolated microscopic hematuria without significant proteinuria. Initial mild renal involvement can occasionally progress to more severe nephritis despite resolution of all other features of HSP. The severity of the systemic manifestations does not correlate with the severity of the nephritis. Most patients who develop nephritis have urinary abnormalities by 1 mo, and nearly all have abnormalities by 3 mo after onset of HSP. Therefore, a urinalysis should be performed weekly in patients with HSP during the period of active clinical disease. Thereafter, a urinalysis should be performed once a month for up to 6 mo. If all urinalyses are normal during this follow-up interval, nephritis is unlikely to develop. If proteinuria, renal insufficiency, or hypertension develops along with hematuria, consultation with a pediatric nephrologist is indicated.

PROGNOSIS AND TREATMENT

The prognosis of HSP nephritis for most patients is excellent. Spontaneous and complete resolution of the nephritis typically occurs in the majority of patients with mild initial manifestations (isolated hematuria with insignificant proteinuria). However, such patients uncommonly can progress to severe renal involvement, including development of chronic renal failure. Patients with acute nephritic or nephrotic syndrome at presentation have a guarded renal prognosis, particularly if they are found to have concomitant necrosis or substantial crescentic changes on renal biopsy. Untreated, the risk of developing chronic kidney disease, including renal failure, is 2-5% in all patients with HSP, but almost 50% in those with the most severe early renal clinical and histologic features.

No studies have demonstrated any efficacy of short courses (weeks) of oral corticosteroids administered promptly after onset of HSP on either preventing the development of nephritis or decreasing the severity of subsequent HSP nephritis. Tonsillectomy has been proposed as an intervention for HSP nephritis, but it also does not appear to have any measurable effect on renal outcome. Mild HSP nephritis does not require treatment, because it usually resolves spontaneously.

Efficacy of treatment for moderate or severe HSP nephritis, which is far more likely to progress to chronic renal failure, is more difficult to assess. Limited prospective controlled trials for severe HSP nephritis have not shown benefit from any therapy studied. Several uncontrolled studies have reported significant benefit from aggressive immunosuppression (high-dose and extended courses of corticosteroids with cyclophosphamide or azathioprine) in patients with poor prognostic features on renal biopsy; such patients are at high risk of progressing to chronic renal failure based on historic controls. Anecdotal reports of treatment of high-risk patients with either plasmapheresis or rituximab have indicated a potential benefit. Balancing the absence of controlled data with the severe side effects of aggressive therapies in patients with poor renal prognostic factors is difficult. Aggressive therapy with careful monitoring may be reasonable in those with the most severe HSP nephritis (>50% crescents on biopsy).

Chapter 516

Rapidly Progressive (Crescentic) Glomerulonephritis

Scott K. Van Why and Ellis D. Avner

"Rapidly progressive" describes the clinical course of several forms of glomerulonephritis whose unifying feature is the histopathologic finding of crescents in the majority of glomeruli (Fig. 516-1). The terms *rapidly progressive glomerulonephritis* (RPGN) and *crescentic glomerulonephritis* (CGN) are synonymous. The natural history of most forms of CGN is rapid and relentless progression to end-stage renal failure.

CLASSIFICATION

CGN can be a severe manifestation of essentially every defined primary and secondary glomerulonephritis (GN), but particular forms of GN are more likely to present as, or evolve into, RPGN (Table 516-1). If no underlying cause is identified by systemic features, serologic testing, or histologic examination, the disease is classified as idiopathic CGN. The incidence of specific etiologies of CGN in children varies widely; certain common themes are shared in all such reports. Patients with systemic vasculitis appear to be particularly prone to develop CGN. Patients with Henoch-Schönlein purpura (HSP), antineutrophil cytoplasmic antibody (ANCA)–mediated GN (microscopic polyangiitis and granulomatosis with polyangiitis), and systemic lupus erythematosus account for the majority of patients with CGN. Postinfectious GN or endocarditis rarely progresses to CGN, but because it is the most common form of GN in childhood it accounts for a significant percentage of patients with CGN in most reports. Membranoproliferative GN and idiopathic disease make up most of the remaining cases of CGN. Immunoglobulin (Ig) A nephropathy, a common GN, only rarely is rapidly progressive. Goodpasture disease often has rapidly progressive GN as a component of the syndrome, but its rarity in childhood results in its making up only a small percentage of children with CGN.

Table 516-1 Classification of Rapidly Progressive ("Crescentic") Glomerulonephritis
PRIMARY
Type I: Anti–glomerular basement membrane antibody disease, Goodpasture syndrome (with pulmonary disease)
Type II: Immune complex mediated
Type III: Pauciimmune (usually antineutrophil cytoplasmic antibody-positive)
SECONDARY
Membranoproliferative glomerulonephritis
Immunoglobulin A nephropathy, Henoch-Schönlein purpura
Poststreptococcal glomerulonephritis
Systemic lupus erythematosus
Polyarteritis nodosa, hypersensitivity angiitis

From Appel GB, Radhakrishnan J: Glomerular disorders and nephrotic syndromes. In Goldman L, Schafer AI, editors: Goldman's Cecil medicine, *ed 24, St. Louis, 2012, Elsevier Saunders, Table 122-3, p. 758.*

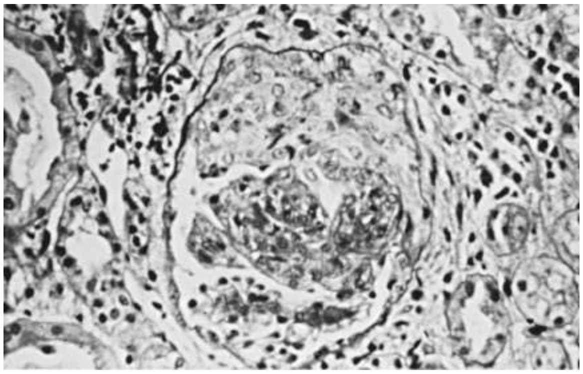

Figure 516-1 Light micrograph of a biopsy specimen from a child with Henoch-Schönlein purpura glomerulonephritis demonstrating a crescent overlying the glomerulus (×180).

PATHOLOGY AND PATHOGENESIS

The hallmark of CGN is the histopathologic finding of crescents in glomeruli (see Fig. 516-1). Crescent formation, through proliferation of parietal epithelial cells in Bowman's space, may be the final pathway of any severe inflammatory glomerular injury. Podocytes and renal progenitor cells are involved in the pathogenesis of CGN. Fibrous crescents, in which proliferative cellular crescents are replaced by collagen, are a late finding. The immunofluorescence findings, as well as the pattern of any deposits by electron microscopy can delineate the underlying glomerulopathy in CGN secondary to lupus, HSP nephritis, membranoproliferative glomerulonephritis, postinfectious GN, IgA nephropathy, or Goodpasture disease. Rare or absent findings by immunofluorescence and electron microscopy typify pauciimmune GN (Wegener disease and microscopic polyangiitis) and idiopathic crescentic GN.

CLINICAL MANIFESTATIONS

Most children present with acute nephritis (hematuria, some degree of renal insufficiency, and hypertension) and usually have concomitant proteinuria, often with nephrotic syndrome. Occasional patients present late in the course of disease with oliguric renal failure. Extrarenal manifestations, such as pulmonary involvement, joint symptoms, or skin lesions, can help lead to the diagnosis of the underlying systemic disease causing the CGN.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of CGN is made by biopsy. Delineation of the underlying etiology is reached by a combination of additional biopsy findings (described earlier), extrarenal symptoms and signs, and serologic testing, including evaluation of antinuclear and anti-DNA antibodies, serum complement levels, and ANCA. If the patient has no extrarenal manifestations and a negative serologic evaluation, and if the biopsy has no immune or electron microscopy deposits, the diagnosis is idiopathic, rapidly progressive CGN.

PROGNOSIS AND TREATMENT

Although the outcome is not uniformly positive, children with crescentic postinfectious GN can spontaneously recover. The natural course of CGN is far more severe in the setting of other etiologies, including the idiopathic category, and progression to end-stage renal failure within weeks to months from onset is common. Having a majority of fibrous crescents on a renal biopsy portends a poor prognosis, because the disease usually has progressed to irreversible injury. Although there are few controlled data, the consensus of most nephrologists is that the combination of high-dose corticosteroids and cyclophosphamide may be effective in preventing progressive renal failure in patients with systemic lupus erythematosus, HSP nephritis, Wegener granulomatosis, and IgA nephropathy if given early in the course when acute cellular crescents predominate. Although such therapy can also be effective in the other diseases causing RPGN, renal outcomes in those settings are less favorable. Progression to end-stage renal disease often occurs despite aggressive immunosuppressive therapy. In combination with immunosuppression, plasmapheresis has been reported to

benefit patients with Goodpasture disease. Plasmapheresis may also benefit patients with ANCA-associated CGN, in particular those with the most severe renal dysfunction at presentation. The possible benefits of plasmapheresis in other forms of RPGN are unclear.

Chapter 517

Goodpasture Disease

Scott K. Van Why and Ellis D. Avner

Goodpasture disease is characterized by pulmonary hemorrhage and glomerulonephritis. The disease results from attack on these organs by antibodies directed against certain epitopes of type IV collagen, located within the alveolar basement membrane in the lung and glomerular basement membrane (GBM) in the kidney. The production of pathologic autoantibody against specific domains in type IV collagen is triggered by an acquired conformational change in α345NC1 hexamers, central structural elements in type IV collagen. The resulting structural alteration reveals neoepitopes that become the target of the pathogenic Goodpasture autoantibody.

PATHOLOGY

Kidney biopsy shows crescentic glomerulonephritis in most patients. Immunofluorescence microscopy demonstrates continuous linear deposition of immunoglobulin G along the GBM (Fig. 517-1).

CLINICAL MANIFESTATIONS

Goodpasture disease is rare in childhood. Patients usually present with hemoptysis from pulmonary hemorrhage that can be life-threatening. Concomitant renal manifestations include acute glomerulonephritis with hematuria, proteinuria, and hypertension, which usually follows a rapidly progressive course. Renal failure commonly develops within days to weeks of clinical presentation. Uncommonly, patients can have anti-GBM nephritis manifesting as isolated, rapidly progressive glomerulonephritis without pulmonary hemorrhage. In essentially all cases, serum anti-GBM antibody is present and complement C3 level is normal. Antineutrophilic cytoplasmic antibody levels can be found to be elevated along with the anti-GBM antibody; such patients doubly positive for these autoantibodies, who have severe disease at presentation, appear to have a more severe prognosis.

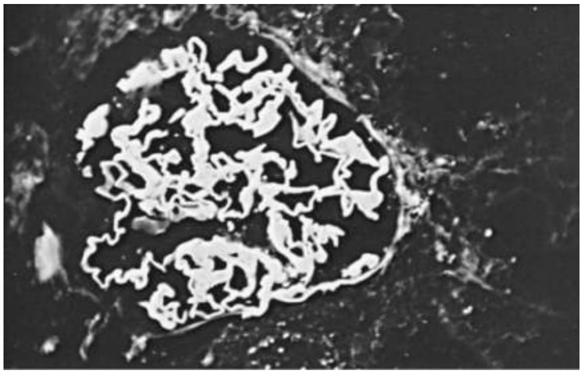

Figure 517-1 Immunofluorescence micrograph demonstrating the continuous linear staining of immunoglobulin G along the glomerular basement membrane in Goodpasture disease (×250).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is made by a combination of the clinical presentation of pulmonary hemorrhage with acute glomerulonephritis, the presence of serum antibodies directed against GBM (anti–type IV collagen in GBM), and characteristic renal biopsy findings. Other diseases that can cause a pulmonary-renal syndrome need to be considered and include systemic lupus erythematosus, Henoch-Schönlein purpura, granulomatosis with polyangiitis, nephrotic syndrome–associated pulmonary embolism, and microscopic polyangiitis. These diseases are ruled out by the absence of other characteristic clinical features, kidney biopsy findings, and negative serologic studies for antibodies against nuclear (antinuclear antibody), DNA (anti-dsDNA), and neutrophil cytoplasmic components (antineutrophilic cytoplasmic antibody).

PROGNOSIS AND TREATMENT

Untreated, the prognosis of Goodpasture disease is poor. The combination of high-dose intravenous methylprednisolone, cyclophosphamide, and plasmapheresis appears to improve survival. Nevertheless, patients who survive the pulmonary hemorrhage often progress to end-stage renal failure despite ongoing immunosuppressive therapy.

Chapter 518

Hemolytic-Uremic Syndrome

Scott K. Van Why and Ellis D. Avner

Hemolytic-uremic syndrome (HUS) is a common cause of community-acquired acute kidney injury in young children. It is characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency. HUS has clinical features in common with thrombotic thrombocytopenic purpura (TTP) (see Chapter 484.5). The etiology and pathophysiology of the more common forms of HUS clearly delineate childhood HUS as separate from idiopathic TTP.

ETIOLOGY

The various etiologies of HUS and other related thrombotic microangiopathies allow classification into infection-induced, genetic, medication- induced, and HUS associated with systemic diseases characterized by microvascular injury (Tables 518-1 and 518-2). The most common form of HUS is caused by toxin-producing *Escherichia coli* that causes prodromal acute enteritis and is commonly termed *diarrhea-associated HUS*. In the subcontinent of Asia and in southern Africa, the toxin of *Shigella dysenteriae* type 1 is causative, whereas in Western countries, verotoxin or Shiga-like toxin producing *E. coli* (STEC) is the usual cause.

Several serotypes of *E. coli* can produce the toxin; O157:H7 is most common in Europe and the Americas. A large epidemic of HUS in Europe was caused by Shiga toxin–producing *E. coli* O104:H4. The reservoir of STEC is the intestinal tract of domestic animals, usually cows. Disease commonly is transmitted by undercooked meat or unpasteurized (raw) milk and apple cider. Local outbreaks have followed ingestion of undercooked, contaminated hamburger or other foods cross-contaminated on unwashed cutting boards at fast food restaurants; contaminated municipal water supplies; petting farms; and swimming in contaminated ponds, lakes, or pools. With broad food distribution, wider epidemics have been traced to lettuce, raw spinach, and bean sprouts contaminated with STEC. Less often, STEC has been spread by person-to-person contact within families or child care centers. A rare but distinct entity of infection-triggered HUS is related

Table 518-1 Thrombotic Microangiopathies Overview and Classification

TMA associated with genetic or immune-mediated abnormalities of the complement system
Genetically determined factor H deficiency
Genetic membrane cofactor protein (CD46) abnormalities
Complement factor 1 deficiency
Gain-of-function mutations of complement factor B
Complement C3 mutations
Acquired anti-C3 autoantibodies
Immune-mediated factor H deficiency
TTP associated with genetic or immune-mediated ADAMTS13 abnormalities
Infectious disease–associated TMA
STEC-HUS
Neuraminidase (pneumococcal)–associated TMA
HIV infection
Systemic disease–associated TMA
Antiphospholipid syndrome
Systemic lupus erythematosus
Scleroderma
Malignant hypertension
Malignancy
Pregnancy-associated TMA
TTP
Hemolysis, elevated liver enzymes, and low platelet count syndrome
Postpartum HUS
Drug-associated TMA (>50 substances reported)
Mitomycin
Quinidine
Ticlopidine
Clopidogrel

Gemcitabine
Anti-VEGF
Metabolic disease–associated TMA
Deficiency in cobalamin C metabolism HUS
Transplant-associated TMA
De novo HUS
Recurrent posttransplantation HUS

ADAMTS13, a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; HIV, human immunodeficiency virus; HUS, hemolytic-uremic syndrome; STEC-HUS, Shiga toxin–producing *Escherichia coli* hemolytic-uremic syndrome; TMA, thrombotic microangiopathy; TTP, thrombotic thrombocytopenic purpura; VEGF, vascular endothelial growth factor.

From Ruggenenti P, Cravedi P, Remuzzi G: Thrombotic microangiopathies including hemolytic uremic syndrome. In Floege J, Johnson R, Feehally J, editors: Comprehensive Clinical Nephrology, vol 1, St. Louis, 2010, Elsevier Saunders, pp. 344–355.

to **neuraminidase-producing** *Streptococcus pneumoniae*. HUS develops during acute infection with this organism, typically manifesting as pneumonia with empyema. A thrombotic microangiopathy, similar to HUS or TTP, also can occur in patients with untreated HIV infection.

Genetic forms of HUS (atypical, nondiarrheal) compose the second major category of the disease (see Tables 518-1 and 518-2). Inherited deficiencies of either von Willebrand factor–cleaving protease (ADAMTS13) or complement factor H, I, or B, and defects in vitamin B_{12} metabolism can cause HUS. A specific genetic defect has not been identified in approximately 50% of familial cases transmitted in classic mendelian autosomal dominant or recessive patterns. A major feature characteristic of genetic forms of HUS is the absence of a preceding diarrhea prodrome. Genetic forms of HUS can be indolent and unremitting once they become manifest, or they can have a relapsing pattern precipitated by an infectious illness. The latter feature likely explains the association of many infectious agents with HUS, particularly in reports published before the recognition of the unique pathophysiology of STEC and neuraminidase-producing pneumococci in causing HUS.

HUS can be superimposed on any disease associated with microvascular injury, including malignant hypertension, systemic lupus erythematosus, and antiphospholipid syndrome (see Chapter 484.4). It can also occur following bone marrow or solid organ transplantation, and may be triggered by the use of the calcineurin inhibitors cyclosporine and tacrolimus in that setting. Several other medications also can induce HUS (see Table 518-1).

PATHOLOGY

Kidney biopsies are only rarely performed in HUS because the diagnosis is usually established by clinical criteria and the risks of biopsy are significant during the active phase of the disease. Early glomerular changes include thickening of the capillary walls caused by swelling of endothelial cells and accumulation of fibrillar material between endothelial cells and the underlying basement membrane, causing narrowing of the capillary lumens. Platelet–fibrin thrombi are often seen in glomerular capillaries. Thrombi are also seen in afferent arterioles and small arteries with fibrinoid necrosis of the arterial wall, leading to renal cortical necrosis from vascular occlusion. Late findings include glomerular sclerosis and obsolescence secondary to either severe direct glomerular involvement or glomerular ischemia from arteriolar involvement.

PATHOGENESIS

Microvascular injury with endothelial cell damage is characteristic of all forms of HUS. In the diarrhea-associated form of HUS, enteropathic organisms produce either Shiga toxin or the highly homologous Shiga-like verotoxin both of which directly cause endothelial cell damage. Shiga toxin can directly activate platelets to promote their aggregation. In pneumococcal-associated HUS, neuraminidase cleaves sialic acid on membranes of endothelial cells, red cells, and platelets to reveal the underlying cryptic Thomsen-Friedenreich (T) antigen. Endogenous immunoglobulin M (IgM) recognizes the T antigen and triggers the microvascular angiopathy.

The familial recessive and dominant forms of HUS, including the inherited deficiencies of ADAMTS13 and regulators of the complement cascade, probably predispose patients to developing HUS but do not cause the disease per se, because these patients might not develop HUS until later childhood or even adulthood. In such cases, HUS is often triggered by an inciting event such as an infectious disease. The absence of ADAMTS13 impairs cleavage of von Willebrand factor multimers, which enhances platelet aggregation. Factor H plays a central role in complement regulation, primarily arresting amplification and propagation of complement activation. It is possible that mild endothelial injury that would normally resolve instead evolves to an aggressive microangiopathy because of the inherited deficiencies of these factors.

In each form of HUS, capillary and arteriolar endothelial injury in the kidney leads to localized thrombosis, particularly in glomeruli, causing a direct decrease in glomerular filtration. Progressive platelet aggregation in the areas of microvascular injury results in consumptive thrombocytopenia. Microangiopathic hemolytic anemia results from mechanical damage to red blood cells as they pass through the damaged and thrombotic microvasculature.

CLINICAL MANIFESTATIONS

HUS is most common in preschool and school-age children, but it can occur in adolescents and adults. In HUS caused by toxigenic *E. coli*, onset of HUS occurs a few days after onset of gastroenteritis with fever, vomiting, abdominal pain, and diarrhea. The prodromal intestinal symptoms may be severe and require hospitalization, but they can also be relatively mild and considered trivial. The diarrhea is often bloody, but not necessarily so. Following the prodromal illness, the sudden onset of pallor, irritability, weakness, and lethargy heralds the onset of HUS. Oliguria can be present in early stages but may be masked by ongoing diarrhea, because the prodromal enteritis often overlaps the onset of HUS, particularly with ingestion of large doses of toxin. Thus, patients with HUS can present with either significant dehydration or volume overload, depending on whether the enteritis or renal

Table 518-2 Genetic Abnormalities and Clinical Outcome in Patients with Atypical Hemolytic-Uremic Syndrome

GENE	PROTEIN AFFECTED	MAIN EFFECT	FREQUENCY (%)	RESPONSE TO SHORT-TERM PLASMA THERAPY*	LONG-TERM OUTCOME†	OUTCOME OF KIDNEY TRANSPLANTATION
CFH	Factor H	No binding to endothelium	20-30	Rate of remission: 60% (dose and timing dependent)	Rate of death or ESRD: 70-80%	Rate of recurrence: 80-90%‡
CFHR1/3	Factor HR1, R3	Anti–factor H antibodies	6	Rate of remission 70-80% (plasma exchange combined with immunosuppression)	Rate of ESRD: 30-40%	Rate of recurrence: 20%§
MCP	Membrane cofactor protein	No surface expression	10-15	No definitive indication for therapy	Rate of death or ESRD: <20%	Rate of recurrence: 15-20%§
CFI	Factor I	Low level or low cofactor activity	4-10	Rate of remission: 30-40%	Rate of death or ESRD: 60-70%	Rate of recurrence: 70-80%‡
CFB	Factor B	C3 convertase stabilization	1-2	Rate of remission: 30%	Rate of death or ESRD: 70%	Recurrence in one case
C3	Complement C3	Resistance to C3b inactivation	5-10	Rate of remission: 40-50%	Rate of death or ESRD: 60%	Rate of recurrence: 40-50%

insufficiency from HUS predominates, and the amount of fluid that has been administered.

Patients with pneumococci-associated HUS usually are ill with pneumonia, empyema, and bacteremia when they develop HUS. Onset can be insidious in patients with the genetic forms of HUS, with HUS triggered by a variety of illnesses, including mild, nonspecific gastroenteritis or respiratory tract infections.

HUS can be relatively mild, or can progress to a severe and fatal multisystem disease. Leukocytosis, severe prodromal enteritis, hyponatremia, and antibiotic use portend a severe course, but no presenting features reliably predict the severity of HUS in any given patient. Patients with HUS who appear mildly affected at presentation can rapidly develop severe, multisystem, life-threatening complications. Renal insufficiency can be mild but also can rapidly evolve into severe oliguric or anuric renal failure. The combination of rapidly developing renal failure and severe hemolysis can result in life-threatening hyperkalemia. Volume overload, hypertension, and severe anemia can all develop soon after onset of HUS, and together can precipitate heart failure. Direct cardiac involvement is rare, but pericarditis, myocardial dysfunction, or arrhythmias can occur without predisposing features of hypertension, volume overload, or electrolyte abnormalities.

The majority of patients with HUS have some central nervous system (CNS) involvement. Most have mild manifestations, with significant irritability, lethargy, or nonspecific encephalopathic features. Severe CNS involvement occurs in ≤20% of cases. Seizures and significant encephalopathy are the most common manifestations in those with severe CNS involvement, resulting from focal ischemia secondary to microvascular CNS thrombosis. Small infarctions in the basal ganglion and cerebral cortex have also been reported, but large strokes and intracranial hemorrhage are rare. Hypertension may produce an encephalopathy and seizures. Intestinal complications can be protean and include severe inflammatory colitis, ischemic enteritis, bowel perforation, intussusception, and pancreatitis. Patients can develop petechiae, but significant or severe bleeding is rare despite very low platelet counts.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is made by the combination of microangiopathic hemolytic anemia with schistocytes, thrombocytopenia, and some degree of kidney involvement. The anemia can be mild at presentation, but rapidly progresses. Thrombocytopenia is an invariable finding in the acute phase, with platelet counts usually 20,000-100,000/mm^3. Partial thromboplastin and prothrombin times are usually normal. The Coombs test is negative, with the exception of pneumococci-induced HUS, where the Coombs test is usually positive. Leukocytosis is often present and significant. Urinalysis typically shows microscopic hematuria and low-grade proteinuria. The renal insufficiency can vary from mild elevations in serum blood urea nitrogen and creatinine to acute, anuric kidney failure.

The etiology of HUS is often clear with the presence of a diarrheal prodrome or pneumococcal infection. The presence or absence of toxigenic organisms on stool culture has little role in making the diagnosis of diarrhea-associated, enteropathic HUS. Only a minority of patients infected with those organisms develops HUS, and the organisms that cause HUS may be rapidly cleared. Therefore, the stool culture is often negative in patients who have diarrhea-associated HUS. If no history of diarrheal prodrome or pneumococcal infection is obtained, then evaluation for genetic forms of HUS should be considered, because those patients are at risk for recurrence, have a severe prognosis, and can benefit from different therapy. Other causes of acute kidney injury associated with a microangiopathic hemolytic anemia and thrombocytopenia should be considered and excluded, such as systemic lupus erythematosus, malignant hypertension, and bilateral renal vein thrombosis (see Table 518-1). A kidney biopsy is rarely indicated to diagnose HUS.

PROGNOSIS AND TREATMENT

With early recognition and intensive supportive care, the mortality for diarrhea-associated HUS is <5% in most major medical centers. Up to half of patients may require dialysis support during the acute phase of the disease. Most recover renal function completely, but of surviving patients, 5% remain dependent on dialysis, and up to 30% are left with some degree of chronic renal insufficiency. The prognosis for HUS not associated with diarrhea is more severe. Pneumococci-associated HUS causes increased patient morbidity, with mortality reported as 20%. The familial, genetic forms of HUS can be insidiously progressive or relapsing diseases and have a poor prognosis (see Table

518-2). Identification of specific factor deficiencies in some of these genetic forms provides opportunity for directed therapy to improve outcome.

The primary approach that has substantially improved acute outcome in HUS is early recognition of the disease, monitoring for potential complications, and meticulous supportive care. Supportive care includes careful management of fluid and electrolytes, including prompt correction of volume deficit, control of hypertension, and early institution of dialysis if the patient becomes significantly oliguric or anuric, particularly with hyperkalemia. Early intravenous volume expansion before the onset of oligo anuria may be nephroprotective in diarrhea-associated HUS. Red cell transfusions are usually required as hemolysis can be brisk and recurrent until the active phase of the disease has resolved. In pneumococci-associated HUS, it is critical that **any administered red cells be washed** before transfusion to remove residual plasma, because endogenous IgM directed against the revealed T antigen can play a role in accelerating the pathogenesis of the disease. Platelets should generally not be administered, regardless of platelet count, to patients with HUS because they are rapidly consumed by the active coagulation and theoretically can worsen the clinical course. Despite low platelet counts, serious bleeding is very rare in patients with HUS.

There is no evidence that any therapy directed at arresting the disease process of the most common, diarrhea-associated form of HUS provides benefit, and some can cause harm. Attempts have been made using anticoagulants, antiplatelet agents, fibrinolytic therapy, plasma therapy, immune globulin, and antibiotics. Anticoagulation, antiplatelet, and fibrinolytic therapies are specifically contraindicated because they increase the risk of serious hemorrhage. Antibiotic therapy to clear enteric toxigenic organisms (STEC) can result in increased toxin release, potentially exacerbating the disease, and therefore is not recommended. However, prompt treatment of causative pneumococcal infection is important. The European experience with *E. coli* O104:H4 in adults who were treated with azithromycin demonstrated more rapid elimination of the organism. Furthermore, in vitro evidence suggests that meropenem, rifaximin, and azithromycin downregulate the release and expression of Shiga toxin. Nonetheless in children with *E. coli* O157:H7–associated HUS, antibiotics are considered contraindicated.

Plasma infusion or plasmapheresis has been proposed for patients suffering severe manifestations of HUS with serious CNS involvement. There are no controlled data demonstrating the effectiveness of this approach, and it is specifically contraindicated in those with pneumococcal-associated HUS as it could exacerbate the disease. The use of plasma therapy in STEC-HUS was one of many treatment strategies during one of the largest reported outbreaks of STEC-HUS, which occurred in Europe in 2011. This outbreak was caused by an uncommon serotype (O104:H4) that had unique virulence factors. Thought initially to cause more severe disease, it differed epidemiologically from other STEC-HUS serotypes by affecting primarily healthy adults, rather than the usual pattern of affecting children and the elderly. Treatment in this epidemic included plasma exchange in most of the adult patients, as well as the use of eculizumab.

Eculizumab is an anti-C5 antibody that inhibits complement activation, a pathway that contributes to active disease in some forms of atypical familial HUS; this pathway may contribute to the process in STEC-HUS. Eculizumab is FDA approved for the treatment of atypical HUS. Because of the risk of meningococcal disease in patients with congenital defects in terminal complement components, it is recommended to give the meningococcal vaccine prior to giving eculizumab (if the patient has not been primarily immunized). While initial reports suggested that eculizumab provided benefit in patients with diarrhea-associated HUS, subsequent systematic analysis showed no benefit from either plasma exchange or eculizumab.

Plasma therapy can be of substantial benefit to patients with identified deficits of ADAMTS13 or factor H. It may also be considered in patients with other genetic forms of HUS, such as the undefined familial (recessive or dominant) form or sporadic but recurrent HUS. In contrast to its use in STEC-HUS, eculizumab shows great promise in treatment of atypical HUS, including HUS occurring following renal transplantation. Whether it should be combined with plasma therapy, or used as a primary treatment of atypical HUS, is still undetermined.

Most patients with diarrhea-associated HUS recover completely with little risk of long-term sequelae. Patients with hypertension, any level of renal insufficiency, or residual urinary abnormalities persisting a year after an episode of diarrhea-positive HUS (particularly significant proteinuria) require careful follow-up. Patients who have recovered completely with no residual urinary abnormalities after a yr are unlikely to manifest long-term sequelae. Because of some reports of late sequelae in such patients, annual examinations with a primary physician are still warranted.

519.6 Vascular Abnormalities

Craig C. Porter and Ellis D. Avner

Hemangiomas, hemangiolymphangiomas, angiomyomas, and arteriovenous malformations of the kidneys and lower urinary tract are rare causes of hematuria. They can present clinically with microscopic hematuria or gross hematuria with clots. When associated cutaneous vascular malformations are present, they can offer a clue to these underlying causes of hematuria. Renal colic can develop with any upper tract vascular abnormality that obstructs urinary drainage, induces an inflammatory response, or distends the renal capsule. The diagnosis may be confirmed by angiography or endoscopy.

Unilateral bleeding of varicose veins of the left ureter, resulting from compression of the left renal vein between the aorta and superior mesenteric artery (mesoaortic compression), is referred to as the **nutcracker syndrome.** Patients with this syndrome typically present with

persistent microscopic hematuria (and occasionally, recurrent gross hematuria) that may be accompanied by proteinuria, left lower abdominal pain, left flank pain, or orthostatic hypotension. Diagnosis requires a high degree of suspicion and is confirmed by Doppler ultrasonography, CT, phlebography of the left renal vein, or magnetic resonance angiography.

Bibliography is available at Expert Consult.

519.7 Renal Vein Thrombosis

Craig C. Porter and Ellis D. Avner

EPIDEMIOLOGY

Renal vein thrombosis (RVT) occurs in 2 distinct clinical settings: (1) In newborns and infants, RVT is commonly associated with asphyxia, dehydration, shock, sepsis, congenital hypercoagulable states, and maternal diabetes; and (2) in older children, RVT is seen in patients with nephrotic syndrome, cyanotic heart disease, inherited hypercoagulable states, sepsis, following kidney transplantation, and following exposure to angiographic contrast agents.

PATHOGENESIS

RVT begins in the intrarenal venous circulation and can then extend to the main renal vein and even the inferior vena cava. Thrombus formation is mediated by endothelial cell injury resulting from hypoxia, endotoxin, or contrast media. Other contributing factors include hypercoagulability from either nephrotic syndrome or mutations in genes that encode clotting factors (i.e., factor V Leiden deficiency); hypovolemia and decreased venous blood flow associated with septic shock, dehydration, or nephrotic syndrome; and intravascular sludging caused by polycythemia.

CLINICAL MANIFESTATIONS

The development of RVT is classically heralded by the sudden onset of gross hematuria and unilateral or bilateral flank masses. However, patients can also present with any combination of microscopic hematuria, flank pain, hypertension, or a microangiopathic hemolytic anemia with thrombocytopenia or oliguria. RVT is usually unilateral. Bilateral RVT results in acute kidney failure.

DIAGNOSIS

The diagnosis of RVT is suggested by the development of hematuria and flank masses in patients seen in the high-risk clinical settings or with the predisposing clinical features noted above. Ultrasonography shows marked renal enlargement, and radionuclide studies reveal little or no renal function in the affected kidney(s). Doppler flow studies of the inferior vena cava and renal vein confirm the diagnosis. Contrast studies should be avoided to minimize the risk of further vascular damage.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of RVT includes other causes of hematuria that are associated with rapid development of microangiopathic hemolytic anemia or enlargement of the kidney(s). These include hemolytic-uremic syndrome, hydronephrosis, polycystic kidney disease, Wilms tumor, and intrarenal abscess or hematoma. All patients should be evaluated for congenital and acquired hypercoagulable states.

TREATMENT

The primary treatment of RVT starts with aggressive supportive intensive care, including correction of fluid and electrolyte imbalance and treatment of renal insufficiency. The American College of Chest Physicians recommends that the additional initial treatment of bilateral RVT should include tissue plasminogen activator and unfractionated heparin followed by continued anticoagulation with unfractionated or low-molecular-weight heparin. Treatment recommendations for unilateral RVT with inferior vena cava extension include either unfractionated or low-molecular-weight heparin. There is no consensus as to whether unilateral RVT without extension should be managed with heparin or with supportive therapy alone. Aggressive treatment with thrombolytic agents in all of these clinical settings, as well as antithrombotic prevention of patients with documented thrombotic risk, remains controversial despite such recommendations given the significant risks of bleeding. Evidence-based data, particularly in children, do not exist despite such “best-practice” recommendations. Children with severe hypertension secondary to RVT who are refractory to antihypertensive medications may require nephrectomy.

PROGNOSIS

Perinatal mortality from RVT has decreased significantly over the past 20 yr. Partial or complete renal atrophy is a common sequela of RVT in the neonate, leading to an increased risk of renal insufficiency, renal tubular dysfunction, and systemic hypertension. These complications are also seen in older children. However, recovery of renal function is not uncommon in older children with RVT resulting from nephrotic syndrome or cyanotic heart disease with correction of the underlying etiology.

Bibliography is available at Expert Consult.

519.8 Idiopathic Hypercalciuria

Craig C. Porter and Ellis D. Avner

Idiopathic hypercalciuria, which may be inherited as an autosomal dominant disorder, can clinically present as recurrent gross hematuria, persistent microscopic hematuria, dysuria, or abdominal pain in the absence of stone formation. Hypercalciuria can also accompany conditions resulting in hypercalcemia, such as hyperparathyroidism, vitamin D intoxication, immobilization, and sarcoidosis. Hypercalciuria may be associated with Cushing syndrome, corticosteroid therapy, tubular dysfunction secondary to Fanconi syndrome (Wilson disease, oculocerebrorenal syndrome), Williams syndrome, distal renal tubular acidosis, or Bartter syndrome (see Chapter 531). Hypercalciuria may also be seen in patients with **Dent disease,** which is an X-linked form of nephrolithiasis associated with hypophosphatemic rickets. Although microcrystal formation with consequent tissue irritation is believed to mediate symptoms, the precise mechanism by which hypercalciuria causes hematuria or dysuria is unknown.

DIAGNOSIS

Hypercalciuria is diagnosed by a 24 hr urinary calcium excretion >4 mg/kg. A screening test for hypercalciuria may be performed on a random urine specimen by measuring the calcium and creatinine concentrations. A spot urine calcium : creatinine ratio (mg/dL : mg/dL) >0.2 suggests hypercalciuria in an older child. Normal ratios may be as high as 0.8 in infants <7 mo of age.

TREATMENT

Left untreated, hypercalciuria leads to nephrolithiasis in approximately 15% of cases. Hypercalciuria has also been associated with an increased risk for development of low bone mineral density as well as an increased incidence of urinary tract infections. Idiopathic hypercalciuria has been identified as a risk factor in 40% of children with kidney stones, and a low urinary citrate level has been associated as a risk factor in approximately 38% of this group. Oral thiazide diuretics can normalize urinary calcium excretion by stimulating calcium reabsorption in the proximal and distal tubules. Such therapy can lead to resolution of gross hematuria or dysuria and can prevent nephrolithiasis. The precise indications for thiazide treatment (including its duration if initiated) remain controversial.

In patients with persistent gross hematuria or dysuria, therapy is initiated with hydrochlorothiazide at a dose of 1-2 mg/kg/24 hr as a single morning dose. The dose is titrated upward until the 24 hr urinary calcium excretion is <4 mg/kg and clinical manifestations

resolve. After 1 yr of treatment, hydrochlorothiazide is usually discontinued, but may be resumed if gross hematuria, nephrolithiasis, or dysuria recurs. During hydrochlorothiazide therapy, the serum potassium level should be monitored periodically to avoid hypokalemia. **Potassium citrate** at a dose of 1 mEq/kg/24 hr may also be beneficial, particularly in patients with low urinary citrate excretion and symptomatic dysuria.

Sodium restriction is important because urinary calcium excretion parallels sodium excretion. Importantly, *dietary calcium restriction is not recommended* (except in children with massive calcium intake >250% of recommended dietary allowance by dietary history) because calcium is a critical requirement for growth, and no evidence supports a relationship between decreased calcium intake and decreased urinary calcium levels. This is particularly important given the association of hypercalciuria in some patients with reduced bone mineral density. A number of uncontrolled, small-scale studies support a role for bisphosphonate therapy, which leads to a reduction in urinary calcium excretion and improvement in bone mineral density. Controlled studies are necessary to establish a clear role for such therapy in children with hypercalciuria.

Chapter 520
Hematologic Diseases Causing Hematuria

520.1 Sickle Cell Nephropathy

Craig C. Porter and Ellis D. Avner

Gross or microscopic hematuria may be seen in children with sickle cell disease or sickle trait. Hematuria tends to resolve spontaneously in the majority of children (see Chapters 462.1 and 462.2). With the exception of an association with renal cell carcinoma, clinically apparent renal involvement occurs more commonly in patients with sickle cell disease than in those with sickle cell trait.

ETIOLOGY

The renal manifestations of sickle cell nephropathy (SSN) are generally related to microthrombosis secondary to sickling in the relatively hypoxic, acidic, hypertonic renal medulla where vascular stasis is present. Analgesic use, volume depletion with consequent prerenal failure, infection, and iron-related hepatic disease are independent contributing factors. Glomerular hyperfiltration, mediated by the intrarenal production of prostaglandins and synthesis of nitric oxide, is involved in the pathogenesis of proteinuria and kidney failure in SSN.

PATHOLOGY

Ischemia, papillary necrosis, and interstitial fibrosis are common pathologic findings in SSN. The specific sickle cell glomerular lesion consists of glomerular hypertrophy, with glomerulomegaly and distended capillaries. In addition, a variety of glomerular lesions are also found in SSN; most commonly these include focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis, and thrombotic microangiopathy. The pathophysiology of these specific glomerulonephritic lesions in SSN is poorly understood but is probably associated with the same factors that produce idiopathic or secondary disease as previously described (see Chapters 511-513).

CLINICAL MANIFESTATIONS

Clinical manifestations of SSN include polyuria caused by a urinary concentrating defect, renal tubular acidosis, and proteinuria associated with the glomerular lesions noted above.

Approximately 20-30% of patients with sickle cell disease develop proteinuria. Nephrotic-range proteinuria with or without clinically apparent nephrotic syndrome occurs in up to 30% of patients with SSN, and when present generally heralds progressive renal failure.

TREATMENT

Tubular manifestations have no specific treatment other than those recommended generally for patients with sickle cell disease. However, angiotensin-converting enzyme inhibitors and/or angiotensin II receptor inhibitors can be used to effect a significant reduction in urine protein excretion in patients with daily urine protein excretion exceeding 500 mg, and may slow progression of renal failure. Gross hematuria secondary to papillary necrosis may respond to treatment with ε-aminocaproic acid or desmopressin acetate. Hydroxyurea and newer treatments for sickle cell disease (see Chapter 462.1) have decreased the manifestations of SSN in proportion to the other complications of the primary hemoglobinopathy.

PROGNOSIS

SSN can eventually lead to hypertension, renal insufficiency, and progressive kidney failure. Dialysis and eventual kidney transplantation are successful treatment modalities when kidney failure is irreversible.

Bibliography is available at Expert Consult.

520.2 Coagulopathies and Thrombocytopenia

Craig C. Porter and Ellis D. Avner

Gross or microscopic hematuria may be associated with inherited or acquired disorders of coagulation (hemophilia, disseminated intravascular coagulation, thrombocytopenia). In these cases, however, hematuria is not usually the presenting complaint or a major factor affecting clinical management of outcome (see Chapters 475-484).

Chapter 521

Anatomic Abnormalities Associated with Hematuria

521.1 Congenital Anomalies

Craig C. Porter and Ellis D. Avner

Gross or microscopic hematuria may be associated with many different types of malformations of the urinary tract. The sudden onset of gross hematuria after minor trauma to the flank is often associated with ureteropelvic junction obstruction, cystic kidneys, or enlarged kidneys from any cause (see Chapter 537).

521.2 Autosomal Recessive Polycystic Kidney Disease

Craig C. Porter and Ellis D. Avner

Also previously referred to as **infantile polycystic disease,** autosomal recessive polycystic kidney disease (ARPKD) is an autosomal recessive disorder occurring with an incidence of 1 : 10,000 to 1 : 40,000, and a gene carrier rate in the general population of 1/70. The gene for ARPKD *(PKHD1 [polycystic kidney and hepatic disease])* encodes fibrocystin, a large protein (>4,000 amino acids) with multiple isoforms.

PATHOLOGY

Both kidneys are markedly enlarged and grossly show innumerable cysts throughout the cortex and medulla. Microscopic studies demonstrate dilated, ectatic collecting ducts radiating from the medulla to the cortex, although transient proximal tubule cysts have been reported in the fetus. Development of progressive interstitial fibrosis and tubular atrophy during advanced stages of disease eventually leads to renal failure. ARPKD causes dual-organ disease and should be considered as *ARPKD/congenital hepatic fibrosis*. Liver involvement is characterized by a basic ductal plate abnormality that leads to bile duct proliferation and ectasia, as well as progressive hepatic fibrosis.

PATHOGENESIS

Fibrocystin may form a multimeric complex with proteins of other primary genetic cystic diseases. It appears that altered intracellular signaling from these complexes, located at epithelial apical cell surfaces, intercellular junctions, and basolateral cell surfaces in association with the focal adhesion complex, is a critical feature of disease pathophysiology.

A large number of mutations in *PKHD1* (without identified specific "hot spots") cause disease, and the same mutation can give variable degrees of disease severity in the same family. This clinical observation is consistent with preclinical data demonstrating many environmental and unknown genetic factors affecting disease expression. The false-negative rate for genetic diagnosis is approximately 10%. Limited available information suggests only gross genotype-phenotype correlation: mutations that modify fibrocystin appear to cause less-severe disease than those that truncate fibrocystin.

CLINICAL MANIFESTATIONS

The typical child presents with bilateral flank masses during the neonatal period or in early infancy. ARPKD may be associated with oligohydramnios, pulmonary hypoplasia, respiratory distress, and spontaneous pneumothorax in the neonatal period. Perinatal demise (approximately 25-30%) appears to be associated with truncating mutations. Components of the oligohydramnios complex (Potter syndrome), including low-set ears, micrognathia, flattened nose, limb-positioning defects, and intrauterine growth restriction, may be present at death from pulmonary hypoplasia. Hypertension is usually noted within the first few weeks of life, is often severe, and requires aggressive multidrug therapy for control. Oliguria and acute renal failure are uncommon, but transient hyponatremia, often in the presence of acute renal failure, often responds to diuresis. Renal function is usually impaired but may be initially normal in 20-30% of patients. Approximately 50% of patients with a neonatal-perinatal presentation develop end-stage renal disease (ESRD) by age 10 yr.

ARPKD is increasingly recognized in infants (and, rarely, in adolescents and young adults) with a mixed renal-hepatic clinical picture. Such children and young adults often present with predominantly hepatic manifestations in combination with variable degrees of renal disease. Hepatic disease manifests as portal hypertension, hepatosplenomegaly, gastroesophageal varices, episodes of ascending cholangitis, prominent cutaneous periumbilical veins, reversal of portal vein flow, and thrombocytopenia. Renal findings in patients with a hepatic presentation may range from asymptomatic abnormal renal ultrasonography to systemic hypertension and renal insufficiency. In the newborn, clinical evidence of liver disease by radiologic or clinical laboratory assessment is present in approximately 45% of children and believed to be universal by microscopic evaluation. Natural history studies of ARPKD patients presenting as infants and young children have classified this group in terms of the severity of their dual-organ phenotype: 40% severe renal/severe kidney and 20% of each of the following—severe kidney/mild liver, severe liver/mild kidney, and mild kidney/mild liver.

DIAGNOSIS

The diagnosis of ARPKD is strongly suggested by bilateral palpable flank masses in an infant with pulmonary hypoplasia, oligohydramnios, and hypertension and the absence of renal cysts by sonography of the parents (Fig. 521-1). Markedly enlarged and uniformly hyperechogenic kidneys with poor corticomedullary differentiation are commonly seen on ultrasonography (Fig. 521-2). The diagnosis is supported by clinical and laboratory signs of hepatic fibrosis, pathologic findings of ductal plate abnormalities seen on liver biopsy, anatomic and pathologic proof of ARPKD in a sibling, or parental consanguinity. The diagnosis can be confirmed by genetic testing. The differential diagnosis includes other causes of bilateral renal enlargement and/or cysts, such as multicystic dysplasia, hydronephrosis, Wilms tumor, and bilateral renal vein thrombosis (Tables 521-1 and 521-2).

Nephronophthisis, an autosomal recessive disorder with renal fibrosis, tubular atrophy, and cyst formation is a common cause of ESRD in children and adolescents (Tables 521-1 and 521-2). Associated external findings include retinal degeneration (Senior-Loken syndrome), cerebellar ataxia (Joubert syndrome), and hepatic fibrosis (Boichis disease). Symptoms include polyuria (salt wasting, poor concentrating ability), failure to thrive, and anemia. Hypertension and edema are seen later when ESRD develops. Prenatal diagnostic testing using genetic linkage analysis or direct mutation analysis is available in families with a previously affected child.

Preimplantation genetic diagnosis with in vitro fertilization may avoid the birth of another affected child with ARPKD.

TREATMENT

The current treatment of ARPKD is supportive. Aggressive ventilatory support is often necessary in the neonatal period secondary to pulmonary hypoplasia, hypoventilation, and the respiratory illnesses of prematurity. Careful management of hypertension (angiotensin-converting enzyme inhibitors), fluid and electrolyte abnormalities, osteopenia, and clinical manifestations of renal insufficiency is essential. Children with severe respiratory failure or feeding intolerance from enlarged kidneys can require unilateral or, more commonly, bilateral nephrectomies, prompting the need for renal replacement therapy. For many children approaching ESRD therapy, significant portal hypertension is present. This in combination with the dramatic improvement in liver transplantation survival has led to consideration of dual renal and hepatic transplantation in a carefully selected group of patients. Dual transplantation thus avoids the later development of end-stage liver disease despite successful renal transplantation.

PROGNOSIS

Mortality has improved dramatically, although approximately 30% of patients die in the neonatal period from complications of pulmonary hypoplasia. Neonatal respiratory support and renal replacement therapies have increased the 10 yr survival of children surviving beyond the 1st yr of life to >80%. Fifteen-year survival is currently estimated at 70-80%. Consideration of dual renal and hepatic transplantation and the development of disease-specific therapies for pediatric clinical trials will further positively impact the natural history of ARPKD. An important resource for families of patients is the ARPKD/CHF Alliance (**www.arpkdchf.org**).

521.3 Autosomal Dominant Polycystic Kidney Disease

Craig C. Porter and Ellis D. Avner

Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary human kidney disease, with an incidence of 1/400 to 1/1,000. It is a systemic disorder with possible cyst formation in multiple organs (liver, pancreas, spleen, brain) and the development of saccular cerebral aneurysms.

PATHOLOGY

Both kidneys are enlarged and show cortical and medullary cysts originating from all regions of the nephron.

PATHOGENESIS

Approximately 85% of patients with ADPKD have mutations that map to the *PKD1* gene on the short arm of chromosome 16, which encodes polycystin, a transmembrane glycoprotein. Another 10-15% of ADPKD mutations map to the *PKD2* gene on the long arm of chromosome 4, which encodes polycystin 2, a proposed nonselective cation channel.

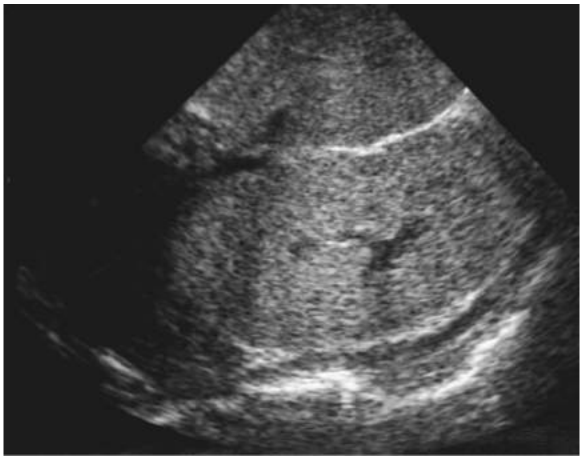

Figure 521-2 Ultrasound examination of a neonate with autosomal recessive polycystic kidney disease demonstrating renal enlargement (9 cm) and increased diffuse echogenicity with complete loss of corticomedullary differentiation resulting from multiple small cystic interfaces.

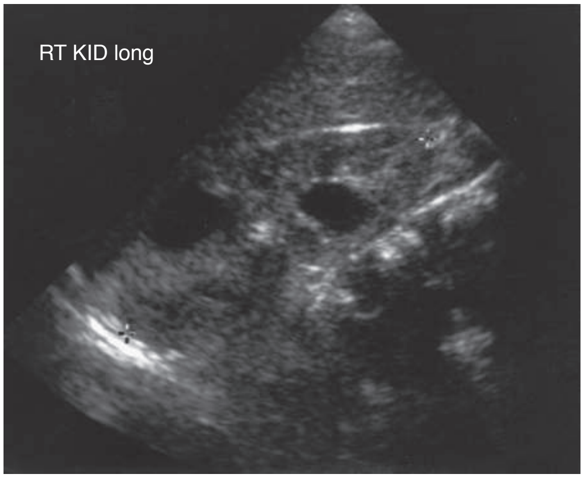

Figure 521-3 Ultrasound examination of an 18 mo old boy with autosomal dominant polycystic kidney disease demonstrating renal enlargement (10 cm) and 2 large cysts.

The majority of mutations appear to be unique to a given family. At present, a mutation can be found in 85% of patients with well-characterized disease. Approximately 8-10% of patients will have de novo, disease-causing mutations. Mutations of *PKD1* are associated with more severe renal disease than mutations of *PKD2*. The pathophysiology of the disease appears to be related to disruption of normal multimeric cystoprotein complexes, with consequent abnormal intracellular signaling resulting in abnormal proliferation, tubular secretion, and cyst formation. Abnormal growth factor expression, coupled with low intracellular calcium and elevated cyclic adenosine monophosphate, appear to be important features leading to formation of cysts and progressive enlargement.

CLINICAL PRESENTATION

The severity of renal disease and the clinical manifestations of ADPKD are highly variable. Although symptomatic ADPKD commonly occurs in the 4th or 5th decade of life, symptoms, including gross or microscopic hematuria, bilateral flank pain, abdominal masses, hypertension, and urinary tract infection, may be seen in neonates, children, and adolescents. With the increased utilization of abdominal sonography in the pediatric population, as well as ADPKD families now requesting possible screening in their asymptomatic, at-risk offspring (with the passage of the Genetic Information Nondiscrimination Act in the United States), most children with ADPKD are diagnosed by abnormal renal sonography in the absence of symptoms. Renal ultrasonography usually demonstrates multiple bilateral macrocysts in enlarged kidneys (Fig. 521-3), although normal kidney size and unilateral disease may be seen in the early phase of the disease in children.

ADPKD is a multiorgan disorder affecting many tissue types. Cysts may be asymptomatic but present within the liver, pancreas, spleen, and ovaries and when present help confirm the diagnosis in childhood. **Intracranial aneurysms,** which appear to segregate within certain families, have an overall prevalence of 15% and are an important cause of mortality in adults, but occasionally occur in children. Mitral valve prolapse is seen in approximately 12% of children; aortic and coronary artery aneurysms and aortic valve insufficiency are noted in affected adults. Hernias, bronchiectasis, and intestinal diverticula can also occur in these children.

DIAGNOSIS

ADPKD is confirmed by the presence of enlarged kidneys with bilateral macrocysts in a patient with an affected 1st-degree relative. De novo mutations occur in 8-10% of patients with newly diagnosed disease. The diagnosis might be made in children before their affected parent, making parental renal sonography an important diagnostic test to be performed in families with no apparent family history. Among patients with genetically defined ADPKD, screening renal ultrasonography results may be normal in ≤20% by 20 yr of age and <5% by 30 yr of age.

Prenatal diagnosis is suggested from the presence of enlarged kidneys with or without cysts on ultrasonography in families with known ADPKD. Prenatal DNA testing is available in families with affected members whose disease is caused by identified mutations in the *PKD1* or *PKD2* genes.

The differential diagnosis includes renal cysts associated with glomerulocystic kidney disease, tuberous sclerosis, and von Hippel-Lindau disease, which may be inherited in an autosomal dominant pattern (see Table 521-1). The neonatal manifestations of ADPKD and ARPKD may rarely be indistinguishable.

TREATMENT AND PROGNOSIS

Treatment of ADPKD is primarily supportive. Control of blood pressure is critical because the rate of disease progression in ADPKD correlates with the presence of hypertension. Angiotensin-converting enzyme inhibitors and/or angiotensin II receptor antagonists are agents of choice. Obesity, caffeine ingestion, smoking, multiple pregnancies, male gender, and possibly the use of calcium channel blockers appear to accelerate disease progression. Older patients with a *family history* of intracranial aneurysm rupture should be screened for cerebral aneurysms.

Although neonatal ADPKD may be fatal, long-term survival of the patient and the kidneys is possible for children surviving the neonatal period. ADPKD that occurs initially in older children has a favorable prognosis, with normal renal function during childhood seen in >80% of children.

Although disease-specific therapy is not yet available, a number of clinical trials are in progress based on promising preclinical laboratory investigation (www.clinicaltrials.gov). A valuable resource for patients and their families is the Polycystic Kidney Disease Foundation (www.pkdcure.org).

decreased muscle mass "protecting" the kidney. Gross or microscopic hematuria, flank pain, and abdominal rigidity can occur; associated injuries may be present (see Chapter 72). In the absence of hemodynamic instability, most renal trauma can be managed nonoperatively. Urethral trauma can result from crush injury, often associated with a fractured pelvis or from direct injury. Such injury is suspected in the appropriate clinical setting when gross blood appears at the external urethral meatus. Rhabdomyolysis and consequent renal failure is another complication of crush injury that can be ameliorated by vigorous fluid resuscitation. There may be a relationship between microscopic hematuria and recreational accidents in individuals >16 yr of age, none of whom exhibited hypotension or required surgical intervention.

Chapter 522
Lower Urinary Tract Causes of Hematuria

522.1 Infectious Causes of Cystitis and Urethritis

Priya Pais and Ellis D. Avner

Gross or microscopic hematuria may be associated with bacterial, mycobacterial, or viral infections of the bladder (see Chapter 538).

522.2 Hemorrhagic Cystitis

Priya Pais and Ellis D. Avner

Hemorrhagic cystitis is defined as the presence of sustained hematuria and lower urinary tract symptoms (e.g., dysuria, frequency, urgency) in the absence of other bleeding conditions such as vaginal bleeding, a generalized bleeding condition, or a bacterial urinary tract infection. Depending on the severity, patients can present with microscopic or gross hematuria, often with clots. In severe forms, bleeding can lead to a significant decrease in blood hemoglobin levels.

Hemorrhagic cystitis can occur in response to chemical toxins (cyclophosphamide, penicillins, busulfan, thiotepa, dyes, insecticides), viruses (adenovirus types 11 and 21 [see Chapter 262] and influenza A), radiation, and amyloidosis. The polyoma BK virus, present latently in immunocompetent hosts, is associated with the development of drug-induced cystitis in immunosuppressed patients. The pediatric bone marrow transplantation population is particularly susceptible to hemorrhagic cystitis.

For chemical irritation related to use of cyclophosphamide, hydration and the use of mesna disulfide, which inactivates urinary cyclophosphamide metabolites, help to protect the bladder. Administration of oral cyclophosphamide in the morning followed by aggressive oral hydration throughout the remainder of the day is very effective in minimizing the risk of hemorrhagic cystitis. Treatment of hemorrhagic cystitis consists of a combination of intensive intravenous hydration, forced diuresis, analgesia, and spasmolytic drugs. Consultation with a urologist is recommended for more invasive measures if the cystitis does not respond to conservative measures. Gross hematuria associated with viral hemorrhagic cystitis usually resolves within 1 wk.

Bibliography is available at Expert Consult.

522.3 Vigorous Exercise

Priya Pais and Ellis D. Avner

Gross or microscopic hematuria can follow vigorous exercise. Exercise hematuria is less common in females and can be associated with dysuria. Approximately 30-60% of runners completing marathons have dipstick-positive urine for blood. In limited follow-up, none appeared to have any significant urinary tract abnormalities. The color of the urine following vigorous exercise can vary from red to black. Blood clots may be rarely present in the urine. Findings on urine culture, intravenous pyelography, voiding cystourethrography, and cystoscopy are normal in most patients. This seems to be a benign condition, and the hematuria generally resolves within 48 hr after cessation of exercise. The absence of red blood cell casts or evidence of renal disease and the presence of dysuria and blood clots in some patients suggest that the source of bleeding lies in the lower urinary tract. **Rhabdomyolysis** with myoglobinuria or hemoglobinuria must be considered in the differential diagnosis when associated with symptoms in the appropriate clinical context. Hydronephrosis or anatomic abnormalities must be considered in any child who presents with hematuria (particularly gross) after mild exercise or following mild trauma. Appropriate imaging studies are indicated in this setting.

Section 3

Conditions Particularly Associated with Proteinuria

Chapter 523

Introduction to the Child with Proteinuria

Priya Pais and Ellis D. Avner

NORMAL PHYSIOLOGY

The charge and size selective properties of the glomerular capillary wall prevent significant amounts of albumin, globulin, and other large plasma proteins from entering the urinary space (see Chapter 508). Smaller proteins (low-molecular-weight proteins) do cross the capillary wall but are reabsorbed by the proximal tubule. A very small amount of protein that normally appears in the urine is the result of normal tubular secretion. The normally excreted protein mostly consists of Tamm-Horsfall protein (uromodulin), a protective glycoprotein secreted by the tubules that inactivates cytokines.

PATHOPHYSIOLOGY OF PROTEINURIA

Abnormal amounts of protein may appear in the urine from 3 possible mechanisms: **glomerular proteinuria**, which occurs as a result of

Table 523-1 Methods Available to Test for Proteinuria

METHOD	INDICATIONS	NORMAL RANGE	COMMENTS
Dipstick testing	Routine screening for proteinuria performed in the office	Negative or trace in a concentrated urine specimen (specific gravity: ≥1.020)	False-positive test can occur if urine is very alkaline (pH > 8.0) or very concentrated (specific gravity: >1.025)
24 hr urine for protein and creatinine* excretion	Quantitation of proteinuria (as well as creatinine clearances)	<100 mg/m^2/24 hr or <150 mg/24 hr in a documented 24 hr collection	More accurate than spot urine analysis; inconvenient for patient; limited use in pediatric practice
Spot urine for protein/creatinine ratio—preferably on first morning urine specimen	Semiquantitative assessment of proteinuria	<0.2 mg protein/mg creatinine in children >2 yr old <0.5 mg protein/mg creatinine in those 6–24 mo old	Simplest method to quantitate proteinuria; less accurate than measuring 24 hr proteinuria
Microalbuminuria	Assess risk of progressive glomerulopathy in patients with diabetes mellitus	<30 mg urine albumin per gram of creatinine on first morning urine	Therapy should be intensified in diabetics with microalbuminuria

*Note that in a 24 hr urine specimen, the creatinine content should be measured to determine whether the specimen is truly a 24 hr collection. The amount of creatinine in a 24 hr specimen can be estimated as follows: females, 15-20 mg/kg; males, 20-25 mg/kg.

Adapted from Hogg RJ, Portman RJ, Milliner D, et al, Evaluation and management of proteinuria and nephrotic syndrome in children: recommendations from a Pediatric Nephrology Panel Established at the National Kidney Foundation Conference on Proteinuria, Albuminuria, Risk Assessment, Detection, and Elimination (PARADE), Pediatrics *105(6):1242–1249, 2000.*

disruption of the glomerular capillary wall; **tubular proteinuria,** a tubular injury or dysfunction that leads to ineffective reabsorption of mostly low-molecular-weight proteins; and **increased production of plasma proteins**—in multiple myeloma, rhabdomyolysis, or hemolysis—which may cause the production or release of very large amounts of protein that are filtered at the glomerulus and overwhelm the absorptive capacity of the proximal tubule.

MEASUREMENT OF URINE PROTEIN

Urine protein can be measured in random collected samples or in timed (e.g., 24 hr or overnight) samples. Tests to accurately quantify urine protein concentration rely on precipitation with sulfosalicylic acid and measurement of turbidity (Table 523-1).

Urine Dipstick Measurement of Protein

Total protein concentration in urine can be estimated with chemically impregnated plastic strips that contain a pH-sensitive colorimetric indicator that changes color when negatively charged proteins, such as albumin, bind to it. Dipsticks primarily detect albuminuria and are less sensitive for other forms of proteins (low-molecular-weight proteins, Bence Jones protein, gamma globulins). Visual changes in the color of the dipstick are a semiquantitative measure of urinary protein concentration. The dipstick is reported as negative, trace (10-29 mg/dL), 1+ (30-100 mg/dL), 2+ (100-300 mg/dL), 3+ (300-1000 mg/dL), and 4+ (>1000 mg/dL). **False-positive** results can occur with a very high urine pH (>7.0), a highly concentrated urine specimen, or contamination of the urine with blood. **False-negative** test results can occur in patients with dilute urine or a large volume of urine output or in disease states in which the predominant urinary protein is not albumin.

Positive urine dipstick test for protein is considered to be present if there is more than a trace (10-29 mg/dL) in a urine sample in which the specific gravity is <1.010. If the specific gravity is >1.015, the dipstick must read ≥1+ (>30 mg/dL) to be considered clinically significant.

Because the dipstick reaction offers only a qualitative measurement of urinary protein excretion, children with persistent proteinuria should have proteinuria quantitated more precisely. **Timed (24 hr) urine collections** offer more precise information regarding urine protein excretion than a randomly performed dipstick test. Urinary protein excretion in the normal child is less than 100 mg/m^2/day or a total of 150 mg/day. In neonates, normal urinary protein excretion is higher, up to 300 mg/m^2, because of reduced reabsorption of filtered proteins. A reasonable upper limit of normal protein excretion in healthy children is 150 mg/24 hr. More specifically, normal protein excretion in children is defined as ≤4 mg/m^2/hr; abnormal proteinuria is defined as excretion of 4-40 mg/m^2/hr; and nephrotic-range proteinuria is defined as >40 mg/m^2/hr.

Timed urine collections are cumbersome to obtain, and the sensitivity and specificity of the test can be influenced by fluid intake, the volume of urine output, and the importance of including a complete collection without missed voids.

Urine Protein-to-Creatinine Ratio Measurement

Urine protein-to-creatinine ratio measurement of an untimed (spot) urine specimen has largely replaced timed urine collection. In children, urine protein-to-creatinine ratios have been shown to significantly correlate with measurements of 24 hr urine protein and are useful to screen for proteinuria and to longitudinally monitor urine protein levels.

This ratio is calculated by dividing the urine protein concentration (mg/dL) by the urine creatinine concentration (mg/dL) to provide a simple measure. It should be ideally performed on a first morning voided urine specimen to eliminate the possibility of orthostatic (postural) proteinuria (see Chapter 525). A ratio of <0.5 in children <2 yr of age and <0.2 in children >2 yr of age suggests normal urinary protein excretion. A ratio greater than 2 suggests nephrotic-range proteinuria.

CLINICAL CONSIDERATIONS

The finding of proteinuria in children and adolescents in a single, non–first morning urine specimen is common, varying between 5% and 15%. The prevalence of persistent proteinuria on repeated testing is much less common. The challenge is to differentiate the child with proteinuria related to renal disease from the otherwise healthy child with transient or other benign forms of proteinuria. When proteinuria is detected it is important to determine if it is transient, orthostatic, or fixed in nature.

Microalbuminuria is defined as the presence of albumin in the urine above the normal level but below the detectable range of conventional urine dipstick methods. In adults, persistent microalbuminuria (defined as a urinary albumin excretion of 30-300 mg/g creatinine on at least 2-3 samples) is accepted as evidence of diabetic nephropathy and also a predictor of cardiovascular and renal disease. The mean level of urinary albumin excretion falls between 8 and 10 mg/g of creatinine in children >6 yr of age. Similar to adults, microalbuminuria in children has been found to be associated with obesity and to predict, with reasonable specificity, the development of diabetic nephropathy in type 1 diabetes mellitus.

Chapter 524

Transient Proteinuria

Craig C. Porter and Ellis D. Avner

The majority of children found to have positive tests for protein on urinary dipsticks will have negative evaluations on repeated dipsticks and normal urinary protein if formally quantitated. Approximately 10% of children who undergo random urinalysis have proteinuria by a single dipstick measurement. Across the school-age spectrum, this finding occurs more commonly in adolescents than in younger children. In most cases, serial testing of the patient's urine demonstrates resolution of the abnormality. This phenomenon defines **transient proteinuria,** and its cause remains elusive. Defined contributing factors include a temperature >38.3°C (101°F), exercise, dehydration, cold exposure, heart failure, seizures, or stress. Transient proteinuria usually does not exceed 1-2+ on the dipstick. No evaluation or therapy is needed for children with this benign condition. Persistence of proteinuria, even if low grade, is not consistent with the diagnosis and suggests the need for additional evaluation.

Bibliography is available at Expert Consult.

Bibliography

Hogg RJ: Adolescents with proteinuria and/or the nephritic syndrome, *Adolesc Med* 16:163–172, 2005.

Increased body mass index is recognized as a strong correlate of orthostatic proteinuria. Long-term follow-up studies in young adults suggest that orthostatic proteinuria is a benign process, but similar data are not available for children. Therefore, long-term follow-up of children is prudent. Patients should be monitored for the development of nonorthostatic proteinuria, particularly in the presence of hematuria, hypertension, or edema. Such findings may herald underlying kidney disease.

Bibliography is available at Expert Consult.

Chapter **525**

Orthostatic (Postural) Proteinuria

Craig C. Porter and Ellis D. Avner

Orthostatic proteinuria is the most common cause of persistent proteinuria in school-age children and adolescents, occurring in up to 60% of children with persistent proteinuria. Children with this condition are usually asymptomatic, and the condition is discovered by routine urinalysis. Patients with orthostatic proteinuria excrete normal or minimally increased amounts of protein in the supine position. In the upright position, urinary protein excretion may be increased 10-fold, up to 1,000 mg/24 hr (1 g/24 hr). *Hematuria, hypertension, hypoalbuminemia, edema, and renal dysfunction are absent.*

In a child with persistent asymptomatic proteinuria, the initial evaluation should include an assessment for orthostatic proteinuria. It begins with the collection of a first morning urine sample, with subsequent testing of any urinary abnormalities by a complete urinalysis and determination of a spot protein : creatinine (Pr : Cr) ratio. The correct collection of the first morning urine sample is critical. The child must fully empty the bladder before going to bed and then collect the first voided urine sample immediately upon arising in the morning. The absence of proteinuria (dipstick negative or trace for protein; and a normal ratio of urinary protein [mg/dL] to urinary creatinine [mg/dL] = [uPr/uCr] <0.2) on the first morning urine sample for 3 consecutive days confirms the diagnosis of orthostatic proteinuria. No further evaluation is necessary, and the patient and family should be reassured of the benign nature of this condition. However, if there are other abnormalities of the urinalysis (e.g., hematuria), or if the urine uPr : uCr ratio is >0.2, the patient should be referred to a pediatric nephrologist for a complete evaluation.

The cause of orthostatic proteinuria is unknown, although altered renal hemodynamics and partial left renal vein obstruction in the upright, lordotic position have been proposed as possible causes.

Chapter 526

Fixed Proteinuria

Priya Pais and Ellis D. Avner

Children found to have fixed proteinuria on a first morning urine sample on 3 separate occasions should be further investigated. Fixed proteinuria is defined as a first morning urine sample that is ≥1+ on dipstick testing with a urine specific gravity >1.015 or with a protein-to-creatinine ratio of ≥0.2. Fixed proteinuria indicates a potential kidney disease caused by either glomerular or tubular disorders.

526.1 Glomerular Proteinuria

Priya Pais and Ellis D. Avner

The glomerular capillary wall consists of 3 layers: the fenestrated capillary endothelium, the glomerular basement membrane, and the podocytes (with foot processes and intercalated slit diaphragms) (Fig. 526-1). Glomerular proteinuria results from alterations in the permeability of any of the layers of the glomerular capillary wall to normally filtered proteins and occurs in a variety of renal diseases (Table 526-1). Glomerular proteinuria can range widely from <1 g to >30 g of protein in a 24 hr period. The podocyte is the predominant cell of injury in most glomerular diseases characterized by heavy proteinuria.

Glomerular proteinuria should be suspected in any patient with a first morning urine protein : creatinine ratio >1.0, or significant proteinuria of any degree, accompanied by hypertension, hematuria, edema, or renal dysfunction (elevated blood urea nitrogen, creatinine). Disorders characterized primarily by proteinuria include idiopathic (minimal change) nephrotic syndrome, focal segmental glomerulosclerosis, mesangial proliferative glomerulonephritis, membranous nephropathy, membranoproliferative glomerulonephritis, diabetic nephropathy, and obesity-related glomerulopathy. Other renal disorders that can include proteinuria as a prominent feature include acute postinfectious glomerulonephritis, immunoglobulin A nephropathy, lupus nephritis, Henoch-Schönlein purpura nephritis, and Alport syndrome.

Initial evaluation of a child with fixed proteinuria should include measurement of serum creatinine and electrolyte panel, first morning urine protein : creatinine ratio, serum albumin level, and complement levels. The child should be referred to a pediatric nephrologist for further evaluation and management. Renal biopsy is often necessary to establish a diagnosis and guide therapy.

In asymptomatic patients with low-grade proteinuria (protein : creatinine ratio between 0.2 and 1.0) in whom all other findings are normal, renal biopsy might not be indicated because the underlying process may be transient or resolving or because specific pathologic features of a chronic kidney disease might not yet be apparent. Such patients should have periodic reevaluation (ideally every 4-6 mo unless the patient is symptomatic). The evaluation should consist of a physical examination with accurate blood pressure measurement, urinalysis, measurement of serum creatinine and a repeat first morning urine

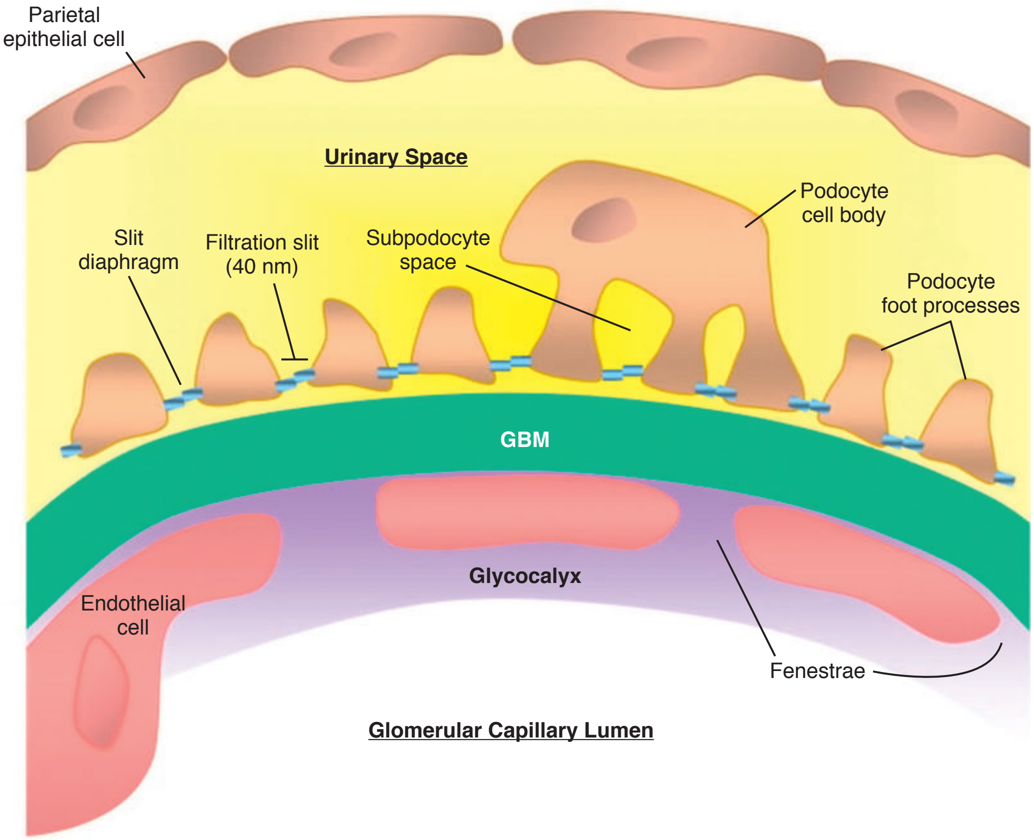

Figure 526-1 **Glomerular capillary wall.** The 3 layers of the capillary wall (glomerular endothelial cell, glomerular basement membrane [GBM], and podocyte) act as the glomerular filtration barrier (GFB), preventing proteins and large molecules from passing from the capillary lumen into the urinary space. The podocyte cell body lies with in the urinary space, and the cell is attached to the GBM through foot processes. Adjacent foot processes are separated by the filtration slit, bridged by the slit diaphragm. Disruption of the GFB leads the passage of protein across the capillary wall, leading to proteinuria. *(From Jefferson JA, Nelson PJ, Najafian B, Shankland SJ. Podocyte disorders: core curriculum 2011.* Am J Kidney Dis *58:666–677, 2011, Fig 1.)*

protein : creatinine ratio. Indications for renal biopsy include increasing proteinuria (protein : creatinine >1.0) or the development of hematuria, hypertension, or diminished renal function.

Bibliography is available at Expert Consult.

526.2 Tubular Proteinuria

Priya Pais and Ellis D. Avner

A variety of renal disorders that primarily involve the tubulointerstitial compartment of the kidney can cause low-grade fixed proteinuria (protein : creatinine ratio 0.2 : 1.0). In the healthy state, large amounts of proteins of lower molecular weight than albumin are filtered by the glomerulus and reabsorbed in the proximal tubule. Injury to the proximal tubules can result in diminished reabsorptive capacity and the loss of these low-molecular-weight proteins in the urine.

Tubular proteinuria (see Table 526-1) may be seen in acquired and inherited disorders and may be associated with other defects of proximal tubular function, such as the Fanconi syndrome (glycosuria, phosphaturia, bicarbonate wasting, and aminoaciduria). Tubular proteinuria is a consistent finding among patients with the X-linked tubular syndrome, Dent disease, caused by mutations of the renal chloride channel.

Asymptomatic patients having persistent proteinuria generally have glomerular rather than tubular proteinuria. In occult cases, glomerular and tubular proteinuria can be distinguished by electrophoresis of the urine. In tubular proteinuria, little or no albumin is detected, whereas in glomerular proteinuria, the major protein is albumin.

Chapter 527
Nephrotic Syndrome

Priya Pais and Ellis D. Avner

Nephrotic syndrome is the clinical manifestation of glomerular diseases associated with heavy (nephrotic-range) proteinuria. Nephrotic-range proteinuria is defined as proteinuria >3.5 g/24 hr or a urine protein : creatinine ratio >2. The **triad of clinical findings associated with nephrotic syndrome** arising from the large urinary losses of protein are hypoalbuminemia (≤2.5 g/dL), edema, and hyperlipidemia (cholesterol >200 mg/dL).

Nephrotic syndrome affects 1-3 per 100,000 children <16 yr of age. Without treatment, nephrotic syndrome in children is associated with a high risk of death, most commonly from infections. Fortunately, 80% of children with nephrotic syndrome respond to corticosteroid therapy. Although glucocorticoid therapy is standard therapy for nephrotic syndrome, neither the target cell nor the mechanism of action of steroids has been determined. Early referral to a pediatric nephrologist is recommended for initial management of nephrotic syndrome. However, continued care of these children is always a collaborative effort between the nephrologist and the primary care physician.

ETIOLOGY

Most children with nephrotic syndrome have a form of **primary** or idiopathic nephrotic syndrome (Table 527-1). Glomerular lesions associated with idiopathic nephrotic syndrome include minimal change disease (the most common), focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis, C3 glomerulopathy, and membranous nephropathy (Table 527-2). These etiologies have different age distributions (Fig. 527-1). Nephrotic syndrome may also be **secondary** to systemic diseases such as systemic lupus erythematosus, Henoch-Schönlein purpura, malignancy (lymphoma and leukemia), and infections (hepatitis, HIV, and malaria) (see Table 527-1). A number of **hereditary** proteinuria syndromes are caused by mutations in genes that encode critical protein components of the glomerular filtration apparatus (Table 527-3).

PATHOGENESIS

Role of the Podocyte

The underlying abnormality in nephrotic syndrome is an increased permeability of the glomerular capillary wall, which leads to massive proteinuria and hypoalbuminemia. The podocyte plays a crucial role in the development of proteinuria and progression of glomerulosclerosis. The podocyte is a highly differentiated epithelial cell located on the outside of the glomerular capillary loop (see Chapter 508.1). Foot processes are extensions of the podocyte that terminate on the glomerular basement membrane. The foot processes of a podocyte interdigitate with those from adjacent podocytes and are connected by a slit called the slit diaphragm. The podocyte functions as structural support of the capillary loop, is a major component of the glomerular filtration barrier to proteins, and is involved in synthesis and repair of the glomerular basement membrane. The slit diaphragm is one of the major impediments to protein permeability across the glomerular capillary wall. Slit diaphragms are not simple passive filters—they consist of numerous proteins that contribute to complex signaling pathways and play an important role in podocyte function. Important component proteins of the slit diaphragm include nephrin, podocin, CD2AP, and α-actinin 4. Podocyte injury or genetic mutations of genes producing podocyte proteins may cause nephrotic-range proteinuria (see Table 527-3).

In idiopathic, hereditary, and secondary forms of nephrotic syndrome, there are immune and nonimmune insults to the podocyte that lead to foot process effacement of the podocyte, a decrease in number of functional podocytes, and altered slit diaphragm integrity. The end result is increased protein "leakiness" across the glomerular capillary wall into the urinary space.

Role of the Immune System

Minimal change nephrotic syndrome (MCNS) may occur after viral infections and allergen challenges. MCNS has also been found to occur in children with Hodgkin lymphoma and T-cell lymphoma. That immunosuppression occurs with drugs such as corticosteroids and cyclosporine provides indirect additional evidence that the immune system contributes to the overall pathogenesis of the nephrotic syndrome.

CLINICAL CONSEQUENCES OF NEPHROTIC SYNDROME

Edema

Edema is the most common presenting symptom of children with nephrotic syndrome. Despite its almost universal presence, there is uncertainty as to the exact mechanism of edema formation. There are 2 opposing theories, the *underfill hypothesis* and the *overfill hypothesis*, that have been proposed as mechanisms causing nephrotic edema.

The *underfill hypothesis* is based on the fact that nephrotic-range proteinuria leads to a fall in the plasma protein level with a corresponding decrease in intravascular oncotic pressure. This leads to leakage of plasma water into the interstitium, generating edema. As a result of reduced intravascular volume, there is increased secretion of vasopressin and atrial natriuretic factor, which, along with aldosterone, result in increased sodium and water retention by the tubules. Sodium and water retention therefore occur as a consequence of intravascular volume depletion.

This hypothesis does not fit the clinical picture of some patients with edema caused by nephrotic syndrome who have clinical signs of intravascular volume overload, not volume depletion. Treating these patients with albumin alone may not be sufficient to induce a diuresis

Table 527-1 Causes of Childhood Nephrotic Syndrome

IDIOPATHIC NEPHROTIC SYNDROME	SECONDARY CAUSES OF NEPHROTIC SYNDROME
Minimal change disease	Infections
Focal segmental glomerulosclerosis	Endocarditis
Membranous nephropathy	Hepatitides B, C
Glomerulonephritis associated with nephrotic syndrome–membranoproliferative glomerulonephritis, crescentic glomerulonephritis, immunoglobulin A nephropathy	HIV-1
	Infectious mononucleosis
GENETIC DISORDERS ASSOCIATED WITH PROTEINURIA OR NEPHROTIC SYNDROME	Malaria
Nephrotic Syndrome (Typical)	Syphilis (congenital and secondary)
Finnish-type congenital nephrotic syndrome (absence of nephrin)	Toxoplasmosis
Focal segmental glomerulosclerosis (mutations in nephrin, podocin, *MYO1E*, α-actinin 4, TRPC6)	Schistosomiasis
Diffuse mesangial sclerosis (mutations in laminin β_2 chain)	Filariasis
Denys-Drash syndrome (mutations in WT1 transcription factor)	Drugs
Congenital nephrotic syndrome with lung and skin involvement (integrin α-3 mutation)	Captopril
Mitochondrial disorders)	Penicillamine
Proteinuria With or Without Nephrotic Syndrome	Gold
Nail-patella syndrome (mutation in LMX1B transcription factor)	Nonsteroidal antiinflammatory drugs
Alport syndrome (mutation in collagen biosynthesis genes)	Pamidronate
Multisystem Syndromes With or Without Nephrotic Syndrome	Interferon
Galloway-Mowat syndrome	Mercury
Charcot-Marie-Tooth disease	Heroin
Jeune syndrome	Lithium
Cockayne syndrome	Immunologic or Allergic Disorders
Laurence-Moon-Biedl-Bardet syndrome	Vasculitis syndromes
Metabolic Disorders With or Without Nephrotic Syndrome	Castleman disease
Alagille syndrome	Kimura disease
α_1-Antitrypsin deficiency	Beesting
Fabry disease	Food allergens
Glutaric acidemia	Serum sickness
Glycogen storage disease	Associated With Malignant Disease
Hurler syndrome	Lymphoma
Partial lipodystrophy	Leukemia
Mitochondrial cytopathies	Solid tumors
Sickle cell disease	Glomerular Hyperfiltration
	Oligomeganephronia
	Morbid obesity
	Adaptation to nephron reduction

Adapted from Eddy AA, Symons JM: Nephrotic syndrome in childhood, Lancet *362:629–638, 2003.*

without the concomitant use of diuretics. Also, reducing the renin–aldosterone axis with mineralocorticoid receptor antagonists does not result in a marked increase in sodium excretion. With the onset of remission of MCNS, many children will have increased urine output before their urinary protein excretion is measurably reduced.

The *overfill hypothesis* postulates that nephrotic syndrome is associated with primary sodium retention, with subsequent volume expansion and leakage of excess fluid into the interstitium. There is accumulating evidence that the epithelial sodium channel in the distal tubule may play a key role in sodium reabsorption in nephrotic syndrome. The clinical weaknesses of this hypothesis are evidenced by the numerous nephrotic patients who present with an obvious clinical picture of intravascular volume depletion: low blood pressure, tachycardia, and elevated hemoconcentration. Furthermore, amiloride, an epithelial sodium channel blocker, used alone is not sufficient to induce adequate diuresis.

The goal of therapy should be a gradual reduction of edema with judicious use of diuretics, sodium restriction, and cautious use of intravenous albumin infusions, if indicated.

Hyperlipidemia

There are several alterations in the lipid profile in children with nephrotic syndrome, including an increase in cholesterol, triglycerides, low-density lipoprotein, and very-low-density lipoproteins. The high-density lipoprotein level remains unchanged or is low. In adults, this results in an increase in the adverse cardiovascular risk ratio, although the implications for children are not as serious, especially those with steroid-responsive nephrotic syndrome. Hyperlipidemia is thought to be the result of increased synthesis as well as decreased catabolism of lipids. Although commonplace in adults, the use of lipid-lowering agents in children is uncommon.

Increased Susceptibility to Infections

Children with nephrotic syndrome are especially susceptible to infections such as cellulitis, spontaneous bacterial peritonitis, and bacteremia. This occurs as a result of many factors, particularly hypoglobulinemia as a result of the urinary losses of immunoglobulin (Ig) G. In addition, defects in the complement cascade from urinary loss of complement factors (predominantly C3 and C5), as well as alternative pathway factors B and D, lead to impaired opsonization of microorganisms. Children with nephrotic syndrome are at significantly increased risk for infection with encapsulated bacteria and, in particular, pneumococcal disease. **Spontaneous bacterial peritonitis** presents with fever, abdominal pain, and peritoneal signs. Although *Pneumococcus* is the most frequent cause of peritonitis, Gram-negative bacteria also are associated with a significant number of cases. Children with nephrotic syndrome and fever or other signs of infection must be evaluated aggressively, with appropriate cultures drawn, and should be treated promptly and empirically with antibiotics. Peritoneal leukocyte counts >250 are highly suggestive of spontaneous bacterial peritonitis.

Hypercoagulability

Nephrotic syndrome is a hypercoagulable state resulting from multiple factors: vascular stasis from hemoconcentration and intravascular volume depletion, increased platelet number and aggregability, and changes in coagulation factor levels. There is an increase in hepatic production of fibrinogen along with urinary losses of antithrombotic

Table 527-2 Summary of Primary Renal Diseases That Manifest as Idiopathic Nephrotic Syndrome

factors such as antithrombin III and protein S. Deep venous thrombosis may occur in any venous bed, including the cerebral venous sinus, renal vein, and pulmonary veins. The clinical risk is low in children (2-5%) compared to adults, but has the potential for serious consequences.

Bibliography is available at Expert Consult.

527.1 Idiopathic Nephrotic Syndrome

Priya Pais and Ellis D. Avner

Approximately 90% of children with nephrotic syndrome have idiopathic nephrotic syndrome. Idiopathic nephrotic syndrome is associated with primary glomerular disease without an identifiable causative disease or drug. Idiopathic nephrotic syndrome includes multiple histologic types: minimal change disease, mesangial proliferation, focal segmental glomerulosclerosis, membranous nephropathy, and membranoproliferative glomerulonephritis.

PATHOLOGY

In minimal change nephrotic syndrome (**MCNS**) (approximately 85% of total cases of nephrotic syndrome in children), the glomeruli appear normal or show a minimal increase in mesangial cells and matrix. Findings on immunofluorescence microscopy are typically negative, and electron microscopy simply reveals effacement of the epithelial cell foot processes. More than 95% of children with minimal change disease respond to corticosteroid therapy.

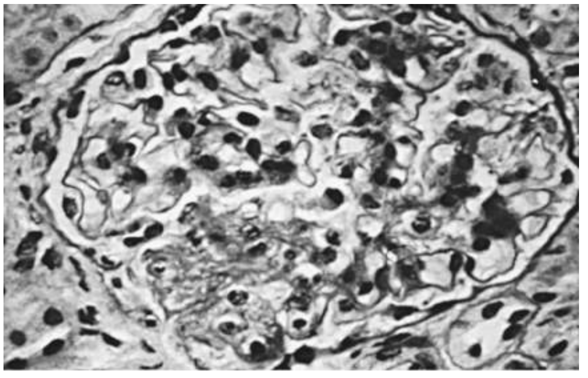

Figure 527-2 Glomerulus from a patient with steroid-resistant nephrotic syndrome showing mesangial hypercellularity and an area of sclerosis in the lower portion (×250).

Mesangial proliferation is characterized by a diffuse increase in mesangial cells and matrix on light microscopy. Immunofluorescence microscopy might reveal trace to 1+ mesangial IgM and/or IgA staining. Electron microscopy reveals increased numbers of mesangial cells and matrix as well as effacement of the epithelial cell foot processes. Approximately 50% of patients with this histologic lesion respond to corticosteroid therapy.

In **focal segmental glomerulosclerosis (FSGS)**, glomeruli show lesions that are both focal (present only in a proportion of glomeruli) and segmental (localized to ≥1 intraglomerular tufts). The lesions consist of mesangial cell proliferation and segmental scarring on light microscopy (Fig. 527-2 and see Table 527-2). Immunofluorescence microscopy is positive for IgM and C3 staining in the areas of segmental sclerosis. Electron microscopy demonstrates segmental scarring of the glomerular tuft with obliteration of the glomerular capillary lumen. Similar lesions may be seen secondary to HIV infection, vesicoureteral reflux, and intravenous use of heroin and other drugs of abuse. Only 20% of patients with FSGS respond to prednisone. The disease is often progressive, ultimately involving all glomeruli, and ultimately leads to end-stage renal disease in most patients.

MINIMAL CHANGE NEPHROTIC SYNDROME

Clinical Manifestations

The idiopathic nephrotic syndrome is more common in boys than in girls (2 : 1) and most commonly appears between the ages of 2 and 6 yr (see Fig. 527-1). However, it has been reported as early as 6 mo of age and throughout adulthood. MCNS is present in 85-90% of patients <6 yr of age. In contrast, only 20-30% of adolescents who present for the first time with nephrotic syndrome have MCNS. The more common cause of idiopathic nephrotic syndrome in this older age group is FSGS. The incidence of FSGS may be increasing; it may be more common in African-American, Hispanic, and Asian patients.

The initial episode of idiopathic nephrotic syndrome, as well as subsequent relapses, usually follows minor infections and, uncommonly, reactions to insect bites, beestings, or poison ivy.

Children usually present with mild edema, which is initially noted around the eyes and in the lower extremities. Nephrotic syndrome can initially be misdiagnosed as an allergic disorder because of the periorbital swelling that decreases throughout the day. With time, the edema becomes generalized, with the development of ascites, pleural effusions, and genital edema. Anorexia, irritability, abdominal pain, and diarrhea are common. Important features of minimal change idiopathic nephrotic syndrome are the absence of hypertension and gross hematuria (the so-called nephritic features).

The differential diagnosis of the child with marked edema includes protein-losing enteropathy, hepatic failure, heart failure, acute or chronic glomerulonephritis, and protein malnutrition. A diagnosis other than MCNS should be considered in children <1 yr of age, with a positive

family history of nephrotic syndrome, and/or the presence of extrarenal findings (e.g., arthritis, rash, anemia), hypertension or pulmonary edema, acute or chronic renal insufficiency, and gross hematuria.

Diagnosis

Recommendations for the Initial Evaluation of Children with Nephrotic Syndrome

Confirming the Diagnosis of Nephrotic Syndrome. The diagnosis of nephrotic syndrome is confirmed by urinalysis with first morning urine protein : creatinine ratio and serum electrolytes, blood urea nitrogen, creatinine, albumin, and cholesterol levels; evaluation to rule out secondary forms of nephrotic syndrome (children ≥10 yr): complement C3 level, antinuclear antibody, double-stranded DNA and hepatitides B and C, and HIV in high-risk populations; and kidney biopsy (for children ≥12 yr, who are less likely to have MCNS).

The urinalysis reveals 3+ or 4+ proteinuria, and microscopic hematuria is present in 20% of children. A spot urine protein : creatinine ratio should be >2.0. The serum creatinine value is usually normal, but it may be abnormally elevated if there is diminished renal perfusion from contraction of the intravascular volume. The serum albumin level is <2.5 g/dL, and serum cholesterol and triglyceride levels are elevated. Serum complement levels are normal. A renal biopsy is not routinely performed if the patient fits the standard clinical picture of MCNS.

Treatment

Children with their first episode of nephrotic syndrome and mild to moderate edema may be managed as outpatients. Such outpatient management is not practiced in all major centers, because the time required for successful education of the family regarding all aspects of the condition can require a short period of hospitalization. The child's parents must be able to recognize the signs and symptoms of the complications of the disease and may be taught how to use a dipstick and interpret the results to monitor for the degree of proteinuria. Tuberculosis must be ruled out prior to starting immunosuppressive therapy with corticosteroids by placing a purified protein derivative or obtaining an interferon release assay, and confirming a negative result.

Children with onset of uncomplicated nephrotic syndrome between 1 and 8 yr of age are likely to have steroid-responsive MCNS, and steroid therapy may be initiated without a diagnostic renal biopsy. Children with features that make MCNS less likely (gross hematuria, hypertension, renal insufficiency, hypocomplementemia, or age <1 yr or >12 yr) should be considered for renal biopsy before treatment.

Use of Corticosteroids to Treat Minimal Change Nephrotic Syndrome

Corticosteroids are the mainstay of therapy for MCNS. The treatment guidelines for corticosteroid use presented below are adapted from and based on the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines on glomerulonephritis.

Treatment of Initial Episode of Nephrotic Syndrome

In children with presumed MCNS, prednisone or prednisolone should be administered as a single daily dose of 60 mg/m^2/day or 2 mg/kg/day to a maximum of 60 mg daily for 4-6 wk followed by alternate-day prednisone (starting at 40 mg/m^2 qod or 1.5 mg/kg qod) for a period ranging from 8 wk to 5 mo, with tapering of the dose. When planning the duration of steroid therapy, the side effects of prolonged corticosteroid administration must be kept in mind.

Approximately 80-90% of children respond to steroid therapy. **Response** is defined as the attainment of remission within the initial 4 wk of corticosteroid therapy. **Remission** consists of a urine protein : creatinine ratio of <0.2 or <1+ protein on urine dipstick for 3 consecutive days. The vast majority of children who respond to prednisone therapy do so within the first 5 wk of treatment.

Managing the Clinical Sequelae of Nephrotic Syndrome

Edema. Children with severe symptomatic edema, including large pleural effusions, ascites, or severe genital edema, should be hospitalized. In addition to sodium restriction (<1500 mg daily), water/fluid restriction may be necessary if the child is hyponatremic. A swollen scrotum may be elevated with pillows to enhance fluid removal by gravity. Diuresis may be augmented by the administration of loop diuretics (furosemide), orally or intravenously**, although extreme caution should be exercised**. Aggressive diuresis can lead to intravascular volume depletion and an increased risk for acute renal failure and intravascular thrombosis.

When a patient has severe generalized edema with evidence of intravascular volume depletion (e.g., hemoconcentration, hypotension, tachycardia), IV administration of 25% albumin (0.5-1.0 g albumin/kg) as a slow infusion followed by furosemide (1-2 mg/kg/dose IV) is sometimes necessary. Such therapy should be used only in collaboration with a pediatric nephrologist and mandates close monitoring of volume status, blood pressure, serum electrolyte balance, and renal function. Symptomatic volume overload, with hypertension, heart failure, and pulmonary edema, is a potential complication of parenteral albumin therapy, particularly when administered as rapid infusions.

Dyslipidemia. Dyslipidemia should be managed with a low-fat diet. Dietary fat intake should be limited to <30% of calories with saturated fat intake <10% calories. Dietary cholesterol intake should be <300 mg/day. There are insufficient data to recommend the use of 3-hydroxy-3-methylgluataryl coenzyme A (HMG-CoA) reductase inhibitors routinely in children with dyslipidemia.

Infections. Families of children with nephrotic syndrome should be counseled regarding the signs and symptoms of infections such as cellulitis, peritonitis, and bacteremia. If there is suspicion of infection, a blood culture should be drawn prior to starting empiric antibiotic therapy. In the case of spontaneous bacterial peritonitis, peritoneal fluid should be collected if there is sufficient fluid to perform a paracentesis and sent for cell count, Gram stain, and culture. The antibiotic provided must be of broad enough coverage to include *Pneumococcus* and Gram-negative bacteria. A 3rd-generation cephalosporin is a common choice of IV antibiotic.

Thromboembolism. Children who present with the clinical signs of thromboembolism should be evaluated by appropriate imaging studies to confirm the presence of a clot. Studies to delineate a specific underlying hypercoagulable state are recommended. Anticoagulation therapy in children with thrombotic events appears to be effective—heparin, low-molecular-weight heparin, and warfarin are therapeutic options.

Obesity and Growth. Glucocorticoids may increase the body mass index in children who are overweight when steroid therapy is initiated, and these children are more likely to remain overweight. Anticipatory dietary counseling is recommended. Growth may be affected in children who require long-term corticosteroid therapy. Steroid-sparing strategies may improve linear growth in children who require prolonged courses of steroids.

Relapse of Nephrotic Syndrome. Relapse of nephrotic syndrome is defined as a urine protein : creatinine ratio of >2 or ≥3+ protein on urine dipstick testing for 3 consecutive days. Relapses are common, especially in younger children, and are often triggered by upper respiratory or gastrointestinal infections. Relapses are usually treated in a manner similar to the initial episode, except that daily prednisone courses are shortened. Daily high-dose prednisone is given until the child has achieved remission, and the regimen is then switched to alternate-day therapy. The duration of alternate day therapy varies depending on the frequency of relapses of the individual child. Children are classified as infrequent relapsers or frequent relapsers, and as being steroid dependent based on the number of relapses in a 12 mo period or their inability to remain in remission following discontinuation of steroid therapy.

Steroid Resistance. Steroid resistance is defined as the failure to achieve remission after 8 wk of corticosteroid therapy. Children with steroid-resistant nephrotic syndrome require further evaluation, including a diagnostic kidney biopsy, evaluation of kidney function, and quantitation of urine protein excretion (in addition to urine dipstick testing). Steroid-resistant nephrotic syndrome is

usually caused by FSGS (80%), MCNS, or membranoproliferative glomerulonephritis.

Implications of Steroid-Resistant Nephrotic Syndrome. Steroid-resistant nephrotic syndrome, and specifically FSGS, is associated with a 50% risk for end-stage kidney disease within 5 yr of diagnosis if patients do not achieve a partial or complete remission. Persistent nephrotic syndrome is associated with poor patient-reported quality of life, hypertension, serious infections, and thromboembolic events. Children reaching end-stage kidney disease have a greatly reduced life expectancy compared to their peers.

Alternative Therapies to Corticosteroids in the Treatment of Nephrotic Syndrome. Steroid-dependent patients, frequent relapsers, and steroid-resistant patients are candidates for alternative therapies, particularly if they have severe corticosteroid toxicity (cushingoid appearance, hypertension, cataracts, and/or growth failure). **Cyclophosphamide** prolongs the duration of remission and reduces the number of relapses in children with **frequently relapsing** and **steroid-dependent** nephrotic syndrome. The potential side effects of the drug (neutropenia, disseminated varicella, hemorrhagic cystitis, alopecia, sterility, increased risk of future malignancy) should be carefully reviewed with the family before initiating treatment. Cyclophosphamide (2 mg/kg) is given as a single oral dose for a total duration of 8-12 wk. Alternate-day prednisone therapy is often continued during the course of cyclophosphamide administration. During cyclophosphamide therapy, the white blood cell count must be monitored weekly and the drug should be withheld if the count falls below 5,000/mm^3. The cumulative threshold dose above which oligospermia or azoospermia occurs in boys is >250 mg/kg.

Calcineurin inhibitors (cyclosporine or tacrolimus) are recommended as initial therapy for children with steroid-resistant nephrotic syndrome. Children must be monitored for side effects, including hypertension, nephrotoxicity, hirsutism, and gingival hyperplasia. **Mycophenolate** can maintain remission in children with steroid-dependent or frequently relapsing nephrotic syndrome. **Levamisole,** an antihelmintic agent with immunomodulating effects that has been shown to reduce the risk of relapse in comparison to prednisone, is not available in the United States. There are also uncontrolled preliminary data regarding prolonged remissions achieved with **rituximab**, the chimeric monoclonal antibody against CD20, in children with steroid-dependent and/or steroid-resistant nephrotic syndrome. There are no data from randomized clinical trials directly comparing the various corticosteroid-sparing agents. Most children who respond to cyclosporine, tacrolimus, or mycophenolate therapy tend to relapse when the medication is discontinued. Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers may be helpful as adjunct therapy to reduce proteinuria in steroid-resistant patients.

Immunizations in Children with Nephrotic Syndrome. To reduce the risk of serious infections in children with nephrotic syndrome, give full pneumococcal vaccination (with the 13-valent conjugant vaccine and 23-valent polysaccharide vaccine) and influenza vaccination annually to the child and their household contacts; defer vaccination with live vaccines until the prednisone dose is below either 1 mg/kg daily or 2 mg/kg on alternate days. Live virus vaccines are contraindicated in children receiving corticosteroid-sparing agents such as cyclophosphamide or cyclosporine. Following close contact with varicella infection, give immunocompromised children on immunosuppressive agents varicella-zoster immune globulin if available; immunize healthy household contacts with live vaccines to minimize the risk of transfer of infection to the immunosuppressed child, but avoid direct exposure of the child to gastrointestinal or respiratory secretions of vaccinated contacts for 3-6 wk after vaccination.

Table 527-4 provides monitoring recommendations for children with nephrotic syndrome.

Prognosis

Most children with steroid-responsive nephrotic syndrome have repeated relapses, which generally decrease in frequency as the child grows older. Although there is no proven way to predict an individual child's course, children who respond rapidly to steroids and those who have no relapses during the first 6 mo after diagnosis are likely to follow an infrequently relapsing course. It is important to indicate to the family that the child with steroid-responsive nephrotic syndrome is unlikely to develop chronic kidney disease, that the disease is rarely hereditary, and that the child (in the absence of prolonged cyclophosphamide therapy) will remain fertile. To minimize the psychologic

effects of the condition and its therapy, children with idiopathic nephrotic syndrome should not be considered chronically ill and should participate in all age-appropriate childhood activities and maintain an unrestricted diet when in remission.

Children with steroid-resistant nephrotic syndrome, most often caused by FSGS, generally have a much poorer prognosis. These children develop progressive renal insufficiency, ultimately leading to end-stage renal disease requiring dialysis or kidney transplantation. Recurrent nephrotic syndrome develops in 30-50% of transplant recipients with FSGS.

527.2 Secondary Nephrotic Syndrome

Priya Pais and Ellis D. Avner

Nephrotic syndrome can occur as a secondary feature of many forms of glomerular disease. Membranous nephropathy, membranoproliferative glomerulonephritis, postinfectious glomerulonephritis, lupus nephritis, and Henoch-Schönlein purpura nephritis can all have a nephrotic component (see Tables 527-1 and 527-2). Secondary nephrotic syndrome should be suspected in patients >8 yr and those with hypertension, hematuria, renal dysfunction, extrarenal symptoms (rash, arthralgias, fever), or depressed serum complement levels. In certain areas of the world, malaria and schistosomiasis are the leading causes of nephrotic syndrome. Other infectious agents associated with nephrotic syndrome include hepatitis B virus, hepatitis C virus, filaria, leprosy, and HIV.

Nephrotic syndrome has been associated with malignancy, particularly in the adult population. In patients with solid tumors, such as carcinomas of the lung and gastrointestinal tract, the renal pathology often resembles membranous glomerulopathy. Immune complexes composed of tumor antigens and tumor-specific antibodies presumably mediate the renal involvement. In patients with lymphomas, particularly Hodgkin lymphoma, the renal pathology most often resembles MCNS. The proposed mechanism of the nephrotic syndrome is that the lymphoma produces a lymphokine that increases permeability of the glomerular capillary wall. Nephrotic syndrome can develop before or after the malignancy is detected, resolve as the tumor regresses, and return if the tumor recurs.

Nephrotic syndrome has also developed during therapy with numerous drugs and chemicals. The histologic picture can resemble membranous glomerulopathy (penicillamine, captopril, gold, nonsteroidal antiinflammatory drugs, mercury compounds), MCNS (probenecid, ethosuximide, methimazole, lithium), or proliferative glomerulonephritis (procainamide, chlorpropamide, phenytoin, trimethadione, paramethadione).

Bibliography is available at Expert Consult.

527.3 Congenital Nephrotic Syndrome

Priya Pais and Ellis D. Avner

Nephrotic syndrome (massive proteinuria, hypoalbuminemia, edema, and hypercholesterolemia) has a poorer prognosis when it occurs in the 1st yr of life, when compared to nephrotic syndrome manifesting in childhood. Congenital nephrotic syndrome is defined as nephrotic syndrome manifesting at birth or within the *1st 3 mo of life*. Congenital nephrotic syndrome may be classified as primary or as secondary to a number of etiologies such as in utero infections (cytomegalovirus, toxoplasmosis, syphilis, hepatitides B and C, HIV), infantile systemic lupus erythematosus, or mercury exposure.

Primary congenital nephrotic syndrome is due to a variety of syndromes inherited as autosomal recessive disorders (see Table 527-3). A number of structural and functional abnormalities of the glomerular filtration barrier causing congenital nephrotic syndrome have been elucidated. In a large European cohort of children with congenital nephrotic syndrome, 85% carried disease-causing mutations in 4 genes (*NPHS1, NPHS2, WT1,* and *LAMB2*), the first 3 of which encode components of the glomerular filtration barrier. The Finnish type of congenital nephrotic syndrome is caused by mutations in the *NPHS1* or *NPHS2* gene, which encodes nephrin and podocin, critical components of the slit diaphragm. Affected infants most commonly present at birth with edema caused by massive proteinuria, and they are typically delivered with an enlarged placenta (>25% of the infant's weight). Severe hypoalbuminemia, hyperlipidemia, and hypogammaglobulinemia result from loss of filtering selectivity at the glomerular filtration barrier. Prenatal diagnosis can be made by the presence of elevated maternal and amniotic α-fetoprotein levels.

Denys-Drash syndrome is caused by mutations in the *WT1* gene, which results in abnormal podocyte function. Patients present with early-onset nephrotic syndrome, progressive renal insufficiency, ambiguous genitalia, and Wilms tumors.

Mutations in the *LAMB2* gene, seen in **Pierson syndrome,** lead to abnormalities of β_2-laminin, a critical component of glomerular and ocular basement membranes. In addition to congenital nephrotic syndrome, affected infants display bilateral microcoria (fixed narrowing of the pupil).

Regardless of the etiology of congenital nephrotic syndrome, diagnosis is made clinically in newborns or infants who demonstrate severe generalized edema, poor growth and nutrition with hypoalbuminemia, increased susceptibility to infections, hypothyroidism (from urinary loss of thyroxin-binding globulin), and increased risk of thrombotic events. Most infants have progressive renal insufficiency.

Secondary congenital nephrotic syndrome can resolve with treatment of the underlying cause, such as syphilis (Table 527-5). The management of primary congenital nephrotic syndrome includes intensive supportive care with intravenous albumin and diuretics, regular administration of intravenous γ-globulin, and aggressive nutritional support (often parenteral), while attempting to pharmacologically decrease urinary protein loss with angiotensin-converting enzyme

inhibitors, angiotensin II receptor inhibitors, and prostaglandin synthesis inhibitors, or even unilateral nephrectomy. If conservative management fails and patients suffer from persistent anasarca or repeated severe infections, bilateral nephrectomies are performed and chronic dialysis is initiated. Renal transplantation is the definitive treatment of congenital nephrotic syndrome, though recurrence of the nephrotic syndrome has been reported to occur after transplantation.

Section 4
Tubular Disorders

Chapter 528
Tubular Function

Rajasree Sreedharan and Ellis D. Avner

Water and electrolytes are freely filtered at the level of the glomerulus. Thus, the electrolyte content of ultrafiltrate at the beginning of the proximal tubule is similar to that of plasma. Carefully regulated processes of tubular reabsorption and/or tubular secretion determine the final water content and electrolyte composition of urine. Bulk movement of solute tends to occur in the proximal portions of the nephron, and fine adjustments tend to occur distally (see Chapter 55).

SODIUM

Sodium is essential in maintaining extracellular fluid balance and, thus, volume status. The kidney is capable of effecting large changes in sodium excretion in a variety of normal and pathologic states.

There are 4 main sites of sodium transport. Approximately 60% of sodium is absorbed in the proximal tubule by coupled transport with glucose or amino acids, 25% in the ascending loop of Henle (mediated by NKCC2, the bumetanide-sensitive sodium-potassium 2 chloride transporter), and 15% in the distal tubule (mediated by NCCT, the thiazide-sensitive sodium chloride cotransporter) and collecting tubule (mediated by ENaC, the epithelial sodium channel).

The urinary excretion of sodium normally approximates the sodium intake of 2-6 mEq/kg/24 hr for a child consuming a typical American diet, minus 1-2 mEq/kg/24 hr required for normal metabolic processes. However, in states of volume depletion (dehydration, blood loss) or decreased effective circulating blood volume (septic shock, hypoalbuminemic states, heart failure), there may be a dramatic decrease in urinary sodium excretion to as low as 1 mEq/L. Changes in systemic volume status are detected by (1) baroreceptors in the atria, afferent arteriole, and carotid sinus and (2) by the macula densa, which detects changes in chloride delivery.

The major hormonal mechanisms mediating sodium balance include the renin–angiotensin–aldosterone axis, atrial natriuretic factor, and norepinephrine. Angiotensin II and aldosterone increase sodium reabsorption in the proximal tubule and distal tubule, respectively. Norepinephrine, released in response to volume depletion, does not directly act on tubular transport mechanisms but affects sodium balance by decreasing renal blood flow, thus decreasing the filtered load of sodium as well as stimulating renin release. With more severe volume depletion, antidiuretic hormone is also released (see Chapter 530). Sodium excretion is promoted by atrial natriuretic factor and suppression of renin.

POTASSIUM

Extracellular potassium homeostasis is regulated because small changes in plasma potassium concentrations have dramatic effects on cardiac, neural, and neuromuscular function (see Chapter 55.4). Essentially, all filtered potassium is fully reabsorbed in the proximal tubule. Therefore, urinary excretion of potassium is completely dependent on tubular secretion by potassium channels present in the principal cells of the collecting tubule. Factors that promote potassium secretion include aldosterone, increased sodium delivery to the distal nephron, and increased urine flow rate.

CALCIUM

A significant portion of filtered calcium (70%) is reabsorbed in the proximal tubule. Additional calcium is reabsorbed in the ascending loop of Henle (20%) and the distal tubule and collecting duct (5-10%). Calcium is reabsorbed by passive movement between cells (paracellular absorption) in a process driven by sodium chloride reabsorption and potassium recycling into the lumen. In addition, calcium uptake is actively regulated by calcium receptors, specific transporters, and calcium channels. Factors that promote calcium reabsorption include parathyroid hormone (released in response to hypocalcemia), calcitonin, vitamin D, thiazide diuretics, and volume depletion (see Chapter 570). Factors that promote calcium excretion include volume expansion, increased sodium intake, and diuretics such as mannitol and furosemide.

PHOSPHATE

The majority of filtered phosphate is reabsorbed in the proximal tubule by active transport. Reabsorption is increased by dietary phosphorus restriction, volume contraction, and growth hormone. Parathyroid hormone and volume expansion increase phosphate excretion.

MAGNESIUM

Approximately 25% of filtered magnesium is reabsorbed in the proximal tubule. Modulation of renal magnesium excretion occurs primarily in the ascending loop of Henle, with some contribution of the distal convoluted tubule. Although specific magnesium transporters have been identified, the precise mechanisms by which they are regulated remain unclear.

ACIDIFICATION AND CONCENTRATING MECHANISMS

Acidification and concentration are addressed in the sections on renal tubular acidosis and nephrogenic diabetes insipidus, respectively (see Chapters 529 and 530).

DEVELOPMENTAL CONSIDERATIONS

Tubular transport capabilities of neonates (especially premature infants) and young infants are less than those of adults. Although nephrogenesis (the formation of new glomerular/tubular units) is complete by about 36 wk of gestation, significant tubular maturation occurs during infancy. Renal tubular immaturity, reduced glomerular filtration rate, decreased concentrating gradient, and diminished responsiveness to antidiuretic hormone are characteristic of young infants. These factors can contribute to impaired regulation of water, solute, and electrolyte and acid–base homeostasis, particularly during times of acute illness.

Chapter 529

Renal Tubular Acidosis

Rajasree Sreedharan and Ellis D. Avner

Renal tubular acidosis (RTA) is a disease state characterized by a normal anion gap (hyperchloremic) metabolic acidosis in the setting of normal or near-normal glomerular filtration rate. There are 4 main types: proximal (type II) RTA, classic distal (type I) RTA, hyperkalemic (type IV) RTA, and combined proximal and distal (type III). Proximal RTA results from impaired bicarbonate reabsorption and distal RTA from failure to secrete acid. Either of these defects may be inherited and persistent from birth or acquired, as is seen more commonly in clinical practice.

NORMAL URINARY ACIDIFICATION

Kidneys contribute to acid–base balance by reabsorption of filtered bicarbonate (HCO_3^-) and excretion of hydrogen ion (H^+) produced every day. Hydrogen ion secretion from tubule cells into the lumen is key in the reabsorption of HCO_3^-, and the formation of titratable acid (H^+ bound to buffers such as HPO_4^{2-}), and ammonium ions (NH_4^+). Because loss of filtered HCO_3^- is equivalent to addition of H^+ to the body, all filtered bicarbonate should be absorbed before dietary H^+ can be excreted. Approximately 90% of filtered bicarbonate is absorbed in the proximal tubule, and the remaining 10% in the distal segments, mostly the thick ascending limb and outer medullary collecting tubule (Fig. 529-1). In the proximal tubule and thick ascending limb of the loop of Henle, H^+ from water is secreted by the Na^+-H^+ exchanger on the luminal membrane. H^+ combines with filtered bicarbonate resulting in the formation of H_2CO_3, which splits into water and CO_2 in the presence of carbonic anhydrase IV. CO_2 diffuses freely back into the cell, combines with OH^- (from H_2O) to form HCO_3^- in the presence of carbonic anhydrase II, and returns to the systemic circulation via a Na^+-HCO_3^- cotransporter situated at the basolateral membrane of the cell. In the collecting tubule, H^+ is secreted into lumen by H^+ATPase (adenosine triphosphatase) and HCO_3^- is returned to the systemic circulation by the HCO_3^--Cl^- exchanger located on the basolateral membrane. The H^+ secreted proximally and distally in excess of the filtered HCO_3^- is excreted in the urine either as titratable acid or as NH_4^+.

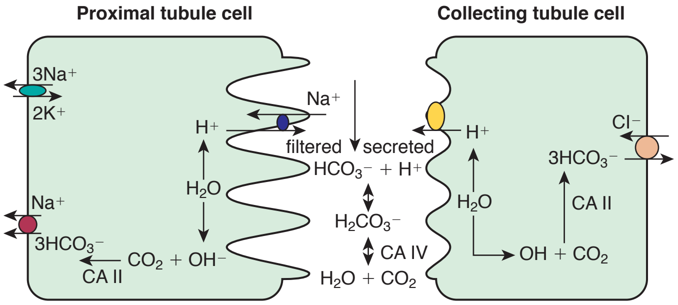

Figure 529-1 **Major cellular luminal events in acid–base regulation in the proximal and the collecting tubule cells.** In the proximal tubule, H^+, split from H_2O, is secreted into the lumen via Na^+/H^+ exchanger, and HCO_3^-, formed by combination of OH^- (split from H_2O) with CO_2 in the presence of carbonic anhydrase (CA) II, is returned to the systemic circulation by an Na^+-$3HCO_3^-$ cotransporter. Similarly, in the collecting tubule, H^+ is secreted into the lumen by an active H^+-ATPase (adenosine triphosphatase), and HCO_3^- is returned to the systemic circulation via an HCO_3^--Cl^- exchanger. H^+ secreted into the lumen combines with filtered HCO_3^- to form carbonic acid (H_2CO_3) and then CO_2 and H_2O in the presence of CA IV, which can be passively reabsorbed. *(Modified from Rose BD, Post TW:* Clinical physiology of acid-base and electrolyte disorders, *ed 5, New York, 2001, McGraw-Hill.)*

529.1 Proximal (Type II) Renal Tubular Acidosis

Rajasree Sreedharan and Ellis D. Avner

PATHOGENESIS

Proximal RTA can be inherited and persistent from birth or occur as a transient phenomenon during infancy. Although rare, it may be primary and isolated. Proximal RTA usually occurs as a component of global proximal tubular dysfunction or **Fanconi syndrome,** which is characterized by low-molecular-weight proteinuria, glycosuria, phosphaturia, aminoaciduria, and proximal RTA. Table 529-1 outlines the causes of proximal RTA (pRTA) and Fanconi syndrome. Many of these causes are inherited disorders. In addition to **cystinosis** and **Lowe syndrome,** autosomal recessive and dominant pRTA are addressed further in this section. Other inherited forms of Fanconi syndrome include **galactosemia** (see Chapter 87.2), **hereditary fructose intolerance** (see Chapter 87.3), **tyrosinemia** (see Chapter 85.2), and **Wilson disease** (see Chapter 357.2). **Dent disease** or X-linked nephrolithiasis, is discussed in Chapter 531.3. In children, an important form of secondary Fanconi syndrome is exposure to ifosfamide, a component of many treatment regimens for Wilms tumor and other solid tumors.

Autosomal Recessive Disease

Isolated **autosomal recessive pRTA** is caused by mutations in the gene encoding the sodium bicarbonate cotransporter NBC1. It manifests with ocular abnormalities (band keratopathy, cataracts, and glaucoma, often leading to blindness), short stature, enamel defects of the teeth, intellectual impairment, and occasionally basal ganglia calcification along with pRTA. Autosomal dominant pattern of inheritance has been identified in a single pedigree with 9 members presenting with hyperchloremic metabolic acidosis, normal ability to acidify urine, normal renal function, and growth retardation.

Cystinosis

Cystinosis is a systemic disease caused by a defect in the metabolism of cysteine that results in accumulation of cystine crystals in most of the major organs of the body, notably the kidney, liver, eye, and brain. It occurs at an incidence of 1 : 100,000 to 1 : 200,000. In certain populations, such as French Canadians, the incidence is much higher. At least 3 clinical patterns have been described. Young children with the most severe form of the disease (*infantile* or *nephropathic cystinosis*) present in the 1st 2 yr of life with severe tubular dysfunction and growth failure. If the disease is not treated, the children develop end-stage renal disease by the end of their 1st decade. A milder form of the disease manifests in adolescents and is characterized by less-severe tubular abnormalities and a slower progression to renal failure. A benign adult form with no renal involvement also exists.

Cystinosis is caused by mutations in the *CTNS* gene, which encodes a novel protein, cystinosin. Cystinosin is thought to be an H^+-driven lysosomal cystine transporter. Genotype–phenotype studies demonstrate that patients with severe nephropathic cystinosis carry mutations that lead to complete loss of cystinosin function. Patients with milder clinical disease have mutations that lead to expression of partially functional protein. Patients with nephropathic cystinosis present with **clinical manifestations** reflecting their pronounced tubular dysfunction and Fanconi syndrome, including polyuria and polydipsia, growth failure, and rickets. Fever, caused by dehydration or diminished sweat production, is common. Patients are typically fair skinned and blond because of diminished pigmentation. Ocular presentations include photophobia, retinopathy, and impaired visual acuity. Patients also can develop hypothyroidism, hepatosplenomegaly, and delayed sexual

maturation. With progressive tubulointerstitial fibrosis, renal insufficiency is invariant.

The **diagnosis** of cystinosis is suggested by the detection of cystine crystals in the cornea and confirmed by measurement of increased leukocyte cystine content. Prenatal testing is available for at-risk families.

Treatment of cystinosis is directed at correcting the metabolic abnormalities associated with Fanconi syndrome or chronic renal failure. In addition, specific therapy is available with **cysteamine,** which binds to cystine and converts it to cysteine. This facilitates lysosomal transport and decreases tissue cystine. Oral cysteamine does not achieve adequate levels in ocular tissues, so additional therapy with cysteamine eyedrops is required. Early initiation of the drug can prevent or delay deterioration of renal function. Patients with growth failure that does not improve with cysteamine might benefit from treatment with growth hormone. Kidney transplantation is a viable option in patients with renal failure. With prolonged survival, additional complications may become evident, including central nervous system abnormalities, muscle weakness, swallowing dysfunction, and pancreatic insufficiency. It is unclear whether long-term cysteamine therapy will decrease these complications.

Lowe Syndrome

Lowe syndrome *(oculocerebrorenal syndrome of Lowe)* is a rare X-linked disorder characterized by congenital cataracts, mental retardation, and Fanconi syndrome. The disease is caused by mutations in the *OCRL1* gene, which encodes the phosphatidylinositol polyphosphate 5-phosphatase protein. The abnormalities seen in Lowe syndrome are thought to be caused by abnormal transport of vesicles within the Golgi apparatus. Kidneys show nonspecific tubulointerstitial changes. Thickening of glomerular basement membrane and changes in proximal tubule mitochondria are also seen.

Patients with Lowe syndrome typically present in infancy with cataracts, progressive growth failure, hypotonia, and Fanconi syndrome. Significant proteinuria is common. Blindness and renal insufficiency often develop. Characteristic behavioral abnormalities are also seen, including tantrums, stubbornness, stereotypy (repetitive behaviors), and obsessions. There is no specific therapy for the renal disease or neurologic deficits. Cataract removal is generally required.

CLINICAL MANIFESTATIONS OF PROXIMAL RENAL TUBULAR ACIDOSIS AND FANCONI SYNDROME

Patients with isolated, sporadic, or inherited pRTA present with growth failure in the 1st yr of life. Additional symptoms can include polyuria, dehydration (from sodium loss), anorexia, vomiting, constipation, and hypotonia. Patients with primary Fanconi syndrome have additional symptoms, secondary to phosphate wasting, such as rickets. Those with systemic diseases present with additional signs and symptoms specific to their underlying disease. *A non–anion gap metabolic acidosis is present*. Urinalysis in patients with isolated pRTA is generally unremarkable. The urine pH is acidic (<5.5) because distal acidification mechanisms are intact in these patients. Urinary indices in patients with Fanconi syndrome demonstrate varying degrees of phosphaturia, aminoaciduria, glycosuria, uricosuria, and elevated urinary sodium or potassium. Depending on the nature of the underlying disorder, laboratory evidence of chronic renal insufficiency, including elevated serum creatinine, may be present.

529.2 Distal (Type I) Renal Tubular Acidosis

Rajasree Sreedharan and Ellis D. Avner

PATHOGENESIS

Distal RTA can be sporadic or inherited. It can also occur as a complication of inherited or acquired diseases of the distal tubules. Primary or secondary causes of distal RTA can result in damaged or impaired functioning of one or more transporters or proteins involved in the acidification process, including the H^+/ATPase, the HCO_3^-/Cl^- anion exchangers, or the components of the aldosterone pathway. Because of impaired hydrogen ion excretion, urine pH cannot be reduced to <5.5, despite the presence of severe metabolic acidosis. Loss of sodium bicarbonate distally, owing to lack of H^+ to bind to in the tubular lumen (see Fig. 529-1), results in increased chloride absorption and hyperchloremia. Inability to secrete H^+ is compensated by increased K^+ secretion distally, leading to hypokalemia. **Hypercalciuria** is usually present and can lead to nephrocalcinosis or nephrolithiasis. Chronic metabolic acidosis also impairs urinary citrate excretion. **Hypocitraturia** further increases the risk of calcium deposition in the tubules. Bone disease is common, resulting from mobilization of organic components from bone to serve as buffers to chronic acidosis.

CLINICAL MANIFESTATIONS

Distal RTA shares features with those of pRTA, including non–anion gap metabolic acidosis and growth failure; distinguishing features of distal RTA include nephrocalcinosis and hypercalciuria. The phosphate and massive bicarbonate wasting characteristic of pRTA is generally absent. Table 529-1 lists the causes of primary and secondary distal RTA. Although inherited forms are rare, 3 specific inherited forms of distal RTA have been identified, including an autosomal recessive form associated with sensorineural deafness.

Medullary sponge kidney is a relatively rare sporadic disorder in children, although not uncommon in adults. It is characterized by cystic dilation of the terminal portions of the collecting ducts as they enter the renal pyramids. Ultrasonographically, patients often have medullary nephrocalcinosis. Although patients with this condition typically maintain normal renal function through adulthood, complications include nephrolithiasis, pyelonephritis, hyposthenuria (inability to concentrate urine), and distal RTA. Associations of medullary sponge kidney with Beckwith-Wiedemann syndrome or hemihypertrophy have been reported.

529.3 Hyperkalemic (Type IV) Renal Tubular Acidosis

Rajasree Sreedharan and Ellis D. Avner

PATHOGENESIS

Type IV RTA occurs as the result of impaired aldosterone production *(hypoaldosteronism)* or impaired renal responsiveness to aldosterone *(pseudohypoaldosteronism)*. Acidosis results because aldosterone has a direct effect on the H^+/ATPase responsible for hydrogen secretion. In addition, aldosterone is a potent stimulant for potassium secretion in the collecting tubule; consequently, lack of aldosterone results in hyperkalemia. This further affects acid–base status by inhibiting ammoniagenesis and, thus, H^+ excretion. Aldosterone deficiency typically occurs as a result of adrenal gland disorders such as Addison disease or some forms of congenital adrenal hyperplasia. In children, aldosterone unresponsiveness is a more common cause of type IV RTA. This can occur transiently, during an episode of acute pyelonephritis or acute urinary obstruction, or chronically, particularly in infants and children with a history of obstructive uropathy. The latter patients can have significant hyperkalemia, even in instances when renal function is normal or only mildly impaired. Rare examples of inherited forms of type IV RTA have been identified.

CLINICAL MANIFESTATIONS

Patients with type IV RTA can present with growth failure in the first few years of life. Polyuria and dehydration (from salt wasting) are common. Rarely, patients (especially those with pseudohypoaldosteronism type 1) present with life-threatening hyperkalemia. Patients with obstructive uropathies can present acutely with signs and symptoms of pyelonephritis, such as fever, vomiting, and foul-smelling urine. Laboratory tests reveal a hyperkalemic non–anion gap metabolic acidosis. Urine may be alkaline or acidic. Elevated urinary sodium levels with inappropriately low urinary potassium levels reflect the absence of aldosterone effect.

DIAGNOSTIC APPROACH TO RENAL TUBULAR ACIDOSIS

The first step in the evaluation of a patient with suspected RTA is to confirm the presence of a normal anion gap metabolic acidosis, identify electrolyte abnormalities, assess renal function, and rule out other causes of bicarbonate loss such as diarrhea (see Chapter 55). Metabolic acidosis associated with diarrheal dehydration is extremely common, and acidosis generally improves with correction of volume depletion. Patients with protracted diarrhea can deplete their total-body bicarbonate stores and can have persistent acidosis despite apparent restoration of volume status. In instances where a patient has a recent history of severe diarrhea, full evaluation for RTA should be delayed for several days to permit adequate time for reconstitution of total-body bicarbonate stores. If acidosis persists beyond a few days in this setting, additional studies are indicated.

Serum electrolytes, blood urea nitrogen, calcium, phosphorus, creatinine, and pH should be obtained by venous puncture. Traumatic blood draws (such as heel-stick specimens), small volumes of blood in "adult-size" specimen collection tubes, or prolonged specimen transport time at room temperature can lead to falsely low bicarbonate levels, often in association with an elevated serum potassium value. True hyperkalemic acidosis is consistent with type IV RTA, whereas the finding of normal or low potassium suggests type I or II. The **blood anion gap** should be calculated using the formula $[Na^+] - [Cl^- + HCO_3^-]$. Values of <12 demonstrate the absence of an anion gap. Values of >20 indicate the presence of an anion gap. If such an anion gap is found, then other diagnoses (lactic acidosis, inborn errors of

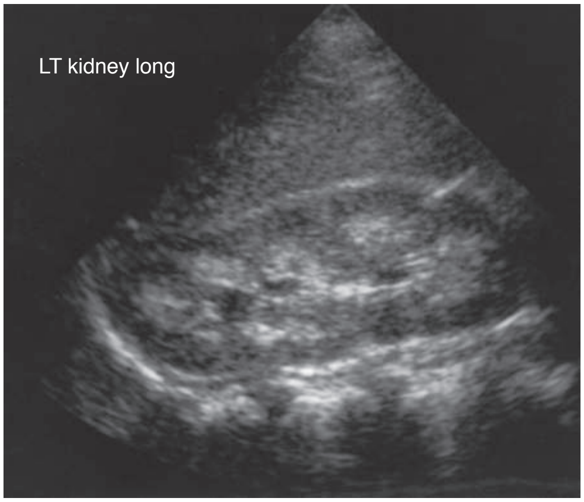

Figure 529-2 Ultrasound examination of a child with distal RTA demonstrating medullary nephrocalcinosis.

metabolism, ingested toxins) should be investigated. If tachypnea is noted, evaluation of an arterial blood gas might help to rule out the possibility of a mixed acid-base disorder primarily involving respiratory and metabolic components. A detailed history, with particular attention to growth and development, recent or recurrent diarrheal illnesses, and a family history of mental retardation, failure to thrive, end-stage renal disease, infant deaths, or miscarriages is essential. Physical examination should determine growth parameters and volume status as well as the presence of any dysmorphic features suggesting an underlying syndrome.

Once the presence of a non–anion gap metabolic acidosis is confirmed, urine pH can help distinguish distal from proximal causes. A urine pH <5.5 in the presence of acidosis suggests pRTA, whereas patients with distal RTA typically have a urine pH >6.0. The **urine anion gap** ([urine Na^+ + urine K^+] – urine Cl^-) is sometimes calculated to confirm the diagnosis of distal RTA. A positive gap suggests a deficiency of ammoniagenesis and, thus, the possibility of a distal RTA. A negative gap is consistent with proximal tubule bicarbonate wasting (gastrointestinal bicarbonate wasting). A urinalysis should also be obtained to determine the presence of glycosuria, proteinuria, or hematuria, suggesting more global tubular damage or dysfunction. Random or 24 hr urine calcium and creatinine measurements will identify hypercalciuria. Renal ultrasonography should be performed to identify underlying structural abnormalities such as obstructive uropathies as well as to determine the presence of nephrocalcinosis (Fig. 529-2).

TREATMENT AND PROGNOSIS

The mainstay of therapy in all forms of RTA is bicarbonate replacement. Patients with pRTA often require large quantities of bicarbonate, up to 20 mEq/kg/24 hr, in the form of sodium bicarbonate or sodium citrate solution (Bicitra or Shohl solution). The base requirement for distal RTAs is generally in the range of 2-4 mEq/kg/24 hr, although patients' requirements can vary. Patients with Fanconi syndrome usually require phosphate supplementation. Patients with distal RTA should be monitored for the development of hypercalciuria. Those with symptomatic hypercalciuria (recurrent episodes of gross hematuria), nephrocalcinosis, or nephrolithiasis can require thiazide diuretics to decrease urine calcium excretion. Patients with type IV RTA can require chronic treatment for hyperkalemia with sodium-potassium exchange resin (Kayexalate).

Prognosis of RTA depends to a large part on the nature of any existing underlying disease. Patients with treated isolated proximal or distal RTA generally demonstrate improvement in growth, provided serum bicarbonate levels can be maintained in the normal range. Patients with systemic illness and Fanconi syndrome can have ongoing morbidity with growth failure, rickets, and signs and symptoms related to their underlying disease.

Bibliography is available at Expert Consult.

529.4 Rickets Associated with Renal Tubular Acidosis

Russell W. Chesney

Rickets may be present in primary RTA, particularly in type II or pRTA. Hypophosphatemia and phosphaturia are common in the renal tubular acidoses, which are also characterized by hyperchloremic metabolic acidosis, various degrees of bicarbonaturia, and, often, hypercalciuria and hyperkaluria. Bone demineralization without overt rickets usually is detected in type I and distal RTA. This metabolic bone disease may be characterized by bone pain, growth retardation, osteopenia, and, occasionally, pathologic fractures. Although acute metabolic acidosis in vitamin D–deficient animals can impair the conversion of 25-hydroxyvitamin D (25[OH]D) to 1,25-dihydroxyvitamin D (1,25[OH]$_2$D), resulting in reduced levels of this active metabolite, the circulating levels of 1,25(OH)$_2$D in patients with either type of RTA are generally normal. If patients with RTA have chronic renal insufficiency, serum 1,25(OH)$_2$D levels are reduced in relation to the degree of renal impairment.

Bone demineralization in distal RTA probably relates to dissolution of bone because the calcium carbonate in bone serves as a buffer against the metabolic acidosis due to the hydrogen ions retained by patients with RTA.

Administration of sufficient bicarbonate to reverse acidosis reverses bone dissolution and the hypercalciuria that is common in distal RTA. Proximal RTA is treated with both bicarbonate and oral phosphate supplements to heal rickets. Doses of phosphate similar to those used in familial hypophosphatemia or Fanconi syndrome may be indicated. Vitamin D is required to offset the secondary hyperparathyroidism that complicates oral phosphate therapy. Following therapy, growth in patients with type II (proximal) RTA is greater than in patients with primary Fanconi syndrome. In addition, "double osteomalacia" may be evident when patients with either type of RTA also have vitamin D deficiency.

Chapter 530

Nephrogenic Diabetes Insipidus

Rajasree Sreedharan and Ellis D. Avner

Nephrogenic diabetes insipidus (NDI) is a rare congenital or, more commonly, acquired, disorder of water metabolism characterized by an inability to concentrate urine, even in the presence of antidiuretic hormone (ADH). The most common pattern of inheritance in congenital NDI is as an X-linked recessive disorder. Rarely, affected females are seen, presumably secondary to partial X-chromosome inactivation. Approximately 10% of cases of congenital NDI are inherited as autosomal dominant or recessive disorders, with males and females affected equally. The clinical phenotype of autosomal recessive forms is similar to that of the X-linked form. Secondary (acquired), either partial or complete, forms of NDI are not uncommon. They may be seen in many disorders affecting renal tubular

function including obstructive uropathies, acute or chronic renal failure, renal cystic diseases, interstitial nephritis, nephrocalcinosis, or toxic nephropathy caused by hypokalemia, hypercalcemia, lithium, or amphotericin B.

PATHOGENESIS

The ability to concentrate urine (and thus absorb water) requires the delivery of urine to the collecting tubule; an intact concentrating gradient in the renal medulla; and the ability to modulate water permeability in the collecting tubule by ADH. ADH (also called arginine vasopressin [AVP]), is synthesized in the hypothalamus and stored in the posterior pituitary. Under basal situations, the collecting tubule is impermeable to water. However, in response to increased serum osmolarity (as detected by osmoreceptors in the hypothalamus) and/or severe volume depletion, ADH is released into the systemic circulation. It then binds to its receptor, vasopressin V_2 (AVPR2), on the basolateral membrane of the collecting tubule cell. Binding of the hormone to its receptor activates a cyclic adenosine monophosphate–dependent cascade that results in movement of preformed water channels (aquaporin 2 [AQP2]) to the luminal membrane of the collecting duct, rendering it permeable to water.

Defects in the *AVPR2* gene cause the more common X-linked form of NDI. Mutations in the *AQP2* gene have been identified in patients with the rarer autosomal dominant and recessive forms. Prenatal testing is available for families at risk for X-linked NDI. Patients with secondary forms of NDI can have ADH resistance owing to defective aquaporin expression (lithium intoxication). Secondary ADH resistance usually occurs as the result of loss of the hypertonic medullary gradient as a result of solute diuresis or tubular damage, resulting in the inability to absorb sodium or urea.

CLINICAL MANIFESTATIONS

Patients with congenital NDI typically present in the newborn period with massive polyuria, volume depletion, hypernatremia, and hyperthermia. Irritability and crying are common features. Constipation and poor weight gain are also seen. After multiple episodes of hypernatremic dehydration, patients can have developmental delay and mental retardation. Enuresis, caused by large urine volumes, is common. Because of the need to consume large volumes of water during the day, patients often have diminished appetite and poor food intake. However, even with adequate caloric supplementation, patients still exhibit growth abnormalities. Patients with congenital NDI also exhibit behavioral problems, including hyperactivity and short-term memory problems. Patients with the secondary form generally present later in life, primarily with hypernatremia and polyuria. Associated symptoms such as developmental delay and behavioral abnormalities are less common in this latter group.

DIAGNOSIS

The diagnosis is suggested in a male infant with polyuria, hypernatremia, and diluted urine. Simultaneous serum and urine osmolality measurements should be obtained. **If the serum osmolality value is 290 mOsm/kg or higher with a simultaneous urine osmolality value of <290 mOsm/kg, a formal water deprivation test is not necessary.** Because the differential diagnosis includes causes of **central diabetes insipidus,** the inability to respond to ADH (and thus the presence of NDI) should then be confirmed by the administration of vasopressin (10-20 μg intranasally) followed by serial urine and serum osmolality measurements hourly for 4 hr. In patients with possible "partial" or secondary diabetes insipidus, in whom the initial serum osmolality value may be <290 mOsm/kg, a water-deprivation test should be considered. Fluids should be withheld and urine and serum osmolalities measured periodically until the serum osmolality value is >290 mOsm/kg; vasopressin is then given as before. Criteria for premature termination of a water-deprivation test include a decrease in body weight of >3%. If NDI is confirmed or suspected, additional evaluation should include a detailed history to assess possible toxic exposures, determination of renal function by serum creatinine and blood urea nitrogen levels, and renal ultrasonography to identify obstructive uropathies or cystic disease. Because of massive urine output, patients with congenital NDI can have *nonobstructive hydronephrosis* of varying severity.

TREATMENT AND PROGNOSIS

Treatment of NDI includes maintenance of adequate fluid intake and access to free water, minimizing urine output by limiting solute load with a low-osmolar, low-sodium diet, and administering medications directed at decreasing urine output. For infants, human milk or a low-solute formula, such as Similac PM 60/40, is preferred. Most infants with congenital NDI require gastrostomy or nasogastric feedings to ensure adequate fluid administration throughout the day and night. Sodium intake in older patients should be <0.7 mEq/kg/24 hr. Thiazide diuretics (2-3 mg/kg/24 hr of hydrochlorothiazide) effectively induce sodium loss and stimulate proximal tubule reabsorption of water. Potassium-sparing diuretics, in particular, amiloride (0.3 mg/kg/24 hr in 3 divided doses), are often indicated. Patients who have an inadequate response to diuretics alone might benefit from the addition of indomethacin (2 mg/kg/24 hr), which has an additive effect in reducing water excretion in some patients. Renal function must be monitored closely in such patients because indomethacin can cause deterioration in renal function over time. Patients with secondary NDI might not require medications but should have access to free water. Such patients should have serum electrolytes and volume status monitored closely, particularly during periods of superimposed acute illnesses.

Prevention of recurrent dehydration and hypernatremia in patients with congenital NDI has significantly improved the neurodevelopmental outcome of these patients. However, behavioral issues remain a significant problem. In addition, chronic use of nonsteroidal antiinflammatory drugs can predispose patients to renal insufficiency. Prognosis of patients with secondary NDI generally depends on the nature of the underlying disease.

Chapter 531

Bartter and Gitelman Syndromes and Other Inherited Tubular Transport Abnormalities

531.1 Bartter Syndrome

Rajasree Sreedharan and Ellis D. Avner

Bartter syndrome is a group of disorders characterized by hypokalemic metabolic alkalosis with hypercalciuria and salt wasting (see Chapter 55) (Table 531-1). **Antenatal** Bartter syndrome (types I, II, and IV; also called **hyperprostaglandin E syndrome**) typically manifests in infancy and has a more-severe phenotype than **classic** Bartter syndrome (type III); perinatal onset includes maternal polyhydramnios, neonatal salt wasting, and severe episodes of recurrent dehydration. The milder

phenotype, **classic** Bartter syndrome, manifests in childhood with failure to thrive and a history of recurrent episodes of dehydration. A phenotypically related disease, Gitelman syndrome, has a distinct genetic defect and is discussed in Chapter 531.2 (Table 531-1). One distinct variant of antenatal Bartter syndrome is associated with sensorineural deafness (type IV).

PATHOGENESIS

The biochemical features of Bartter syndrome, including hypokalemic metabolic alkalosis with hypercalciuria, resemble those seen with chronic use of loop diuretics and reflect a defect in sodium, chloride, and potassium transport in the ascending loop of Henle. The loss of sodium and chloride, with resultant volume contraction, stimulates the renin–angiotensin II–aldosterone axis. Aldosterone promotes sodium uptake and potassium secretion, exacerbating the hypokalemia. It also stimulates hydrogen ion secretion distally, worsening the metabolic alkalosis. Hypokalemia stimulates prostaglandin synthesis, which further activates the renin–angiotensin II–aldosterone axis. Bartter syndrome has been associated with 5 distinct genetic defects in loop of Henle transporters (see Table 531-1). Each contributes, in some manner, to sodium and chloride transport. Mutations in the genes that encode the $Na^+/K^+/2Cl^-$ transporter (NKCC2, the site of action of furosemide), the luminal potassium channel (ROMK), combined chloride channel (CLC-Ka, CLC-Kb), or subunit of chloride channels (barttin) cause neonatal Bartter syndrome. Isolated defects in the genes that produce a specific basolateral chloride channel (ClC-Kb) cause classic Bartter syndrome.

CLINICAL MANIFESTATIONS

A history of maternal polyhydramnios with or without prematurity may be elicited. Dysmorphic features, including triangular facies, protruding ears, large eyes with strabismus, and drooping mouth may be present on physical examination. Consanguinity suggests the presence of an autosomal recessive disorder. Older children can have a history of recurrent episodes of polyuria with dehydration, failure to thrive, nonspecific fatigue, dizziness and chronic constipation. Older children may also present with muscle cramps and weakness secondary to chronic hypokalemia. Blood pressure is usually normal, although patients with the antenatal form can have severe salt wasting, resulting in dehydration and hypotension. Serum chemistry reveals the classic biochemical abnormalities of a hypokalemic metabolic alkalosis. Renal function is typically normal. Urinary calcium levels are typically elevated, as are urinary potassium and sodium levels. Serum renin, aldosterone, and prostaglandin E levels are often markedly elevated, particularly in the more-severe antenatal form. Nephrocalcinosis, resulting from hypercalciuria, may be seen on ultrasound examination (types I and II).

DIAGNOSIS

The diagnosis is usually made based on clinical presentation and laboratory findings. The diagnosis in the neonate or infant is suggested by severe hypokalemia, usually <2.5 mmol/L, with metabolic alkalosis. Hypercalciuria is typical; hypomagnesemia is seen in a minority of patients but is more common in Gitelman syndrome. Because features of Bartter syndrome resemble chronic use of loop diuretics, diuretic abuse should be considered in the differential diagnosis, even in young children. Chronic vomiting can also give a similar clinical picture but can be distinguished by **measurement** of **urinary chloride,** which is elevated in Bartter syndrome and low in patients with chronic vomiting. Kidneys demonstrate hyperplasia of the juxtaglomerular apparatus. Renal biopsy is rarely performed to diagnose this condition.

TREATMENT AND PROGNOSIS

Treatment of Bartter syndrome is directed at preventing dehydration, maintaining nutritional status, and correcting hypokalemia. Potassium supplementation, often at very high doses, is required; potassium-sparing (aldosterone antagonist) diuretics may be of value. Even with appropriate therapy, serum potassium values might not normalize, particularly in patients with the neonatal form. Infants and young children require a high-sodium diet and at times sodium supplementation. Indomethacin, a prostaglandin inhibitor, can also be effective. If hypomagnesemia is present, magnesium supplementation is required. With close attention to electrolyte balance, volume status, and growth, the long-term prognosis is generally good. In a minority of patients, chronic hypokalemia, nephrocalcinosis, and chronic indomethacin therapy can lead to chronic interstitial nephritis and chronic renal failure.

531.2 Gitelman Syndrome

Rajasree Sreedharan and Ellis D. Avner

Gitelman syndrome (often called a "Bartter syndrome variant") is a rare autosomal recessive cause of hypokalemic metabolic alkalosis, with distinct features of **hypocalciuria** and **hypomagnesemia.** Patients with Gitelman syndrome typically present in late childhood or early adulthood (see Table 531-1).

PATHOGENESIS

The biochemical features of Gitelman syndrome resemble those of chronic use of thiazide diuretics. Thiazides act on the sodium chloride cotransporter NCCT, present in the distal convoluted tubule. Through linkage analysis and mutational studies, defects in the gene encoding NCCT have been demonstrated in patients with Gitelman syndrome.

CLINICAL MANIFESTATIONS

Patients with Gitelman syndrome typically present at a later age than those with Bartter syndrome and may have symptoms similar to older children with Bartter syndrome (see Chapter 531.1). Patients often have a history of recurrent muscle cramps and spasms, presumably caused by low serum magnesium levels, nocturia, polyuria, and occasional hypotension. They usually do not have a history of recurrent episodes of dehydration. Biochemical abnormalities include hypokalemia, metabolic alkalosis, and hypomagnesemia. The urinary calcium level is usually very low (in contrast to the elevated urinary calcium level often seen in Bartter syndrome), and the urinary magnesium level is elevated. Renin and aldosterone levels are usually normal, and prostaglandin E secretion is not elevated. Growth failure is less prominent in Gitelman syndrome than in Bartter syndrome.

DIAGNOSIS

The diagnosis of Gitelman syndrome is suggested in an adolescent or adult presenting with hypokalemic metabolic alkalosis, hypomagnesemia, and hypocalciuria.

TREATMENT

Therapy is directed at correcting hypokalemia and hypomagnesemia with supplemental potassium and magnesium. Sodium supplementation or treatment with prostaglandin inhibitors is generally not necessary because patients typically do not have episodes of volume depletion or elevated prostaglandin E excretion.

531.3 Other Inherited Tubular Transport Abnormalities

Rajasree Sreedharan and Ellis D. Avner

Inherited abnormalities in distinct transporters in each segment of the nephron have now been identified and the molecular defects have been characterized. Renal tubular acidosis and nephrogenic diabetes insipidus are discussed in detail in Chapters 529 and 530, respectively. **Cystinuria** is an autosomal recessive disorder seen primarily in patients of Middle Eastern descent and is characterized by recurrent stone formation. The disease is caused by a defective high-affinity transporter for L-cystine and dibasic amino acids present in the proximal tubule.

Dent disease is an X-linked proximal tubulopathy with characteristic abnormalities that include low-molecular-weight proteinuria, hypercalciuria, and other features of Fanconi syndrome, such as glycosuria, aminoaciduria, and phosphaturia. Although some patients develop nephrocalcinosis, nephrolithiasis, progressive renal failure, and hypophosphatemic rickets, patients with Dent disease typically do not have proximal renal tubular acidosis or extrarenal manifestations. Loss-of-function mutations of the *CLCN5* gene, which is located in Xp11.22 and encodes a renal Cl^-/H^+ antiporter (ClC-5), are reported in patients with Dent disease. Genetic heterogeneity of Dent disease in some patients who exhibit mutations in the gene for OCRL1 (responsible for Lowe syndrome) also meets Dent disease criteria: Dent-2 disease. Dent disease includes X-linked recessive nephrolithiasis with renal failure, X-linked recessive hypophosphatemic rickets, and idiopathic low-molecular-weight proteinuria seen in Japanese children.

Mutations in an extracellular basolateral calcium-sensing receptor, normally present in the loop of Henle, can cause a **dominant Bartter syndrome–like picture**. These patients' predominant symptoms are hypocalcemic and suppressed parathyroid hormone function, which differentiates them from patients with Bartter syndrome.

In the distal convoluted tubule, gain-of-function mutations in *WNK1* and loss-of-function mutations in *WNK4*, both serine threonine kinases, lead to excessive NCCT-mediated salt reabsorption with the clinical picture of pseudohypoaldosteronism type 2 (familial hyperkalemic hypertension, or **Gordon syndrome**).

In the collecting duct, gain-of-function mutations of the gene that encodes the epithelial sodium channel cause an inherited form of hypertension, **Liddle syndrome.** Patients with this disorder have constitutive sodium uptake in the collecting duct, with hypokalemia and suppressed aldosterone. Conversely, loss-of-function mutations cause pseudohypoaldosteronism, characterized by severe sodium wasting and hyperkalemia. A variant of the latter disorder is associated with systemic abnormalities, including defects in sweat chloride, and can resemble cystic fibrosis.

Renal hypouricemia, a defect in the *SLC22A12* gene, presents with low serum uric acid levels and is complicated by exercise-induced acute renal failure. Patients have elevated urine uric acid levels and present with loin pain, nausea, and vomiting after exercise. Treatment is for acute renal failure and reducing the intensity of exercise.

Chapter 532

Tubulointerstitial Nephritis

Craig C. Porter and Ellis D. Avner

Tubulointerstitial nephritis (TIN, also called interstitial nephritis) is the term applied to conditions characterized by tubulointerstitial inflammation and damage with relative sparing of glomeruli and vessels. Both acute and chronic primary forms exist. Interstitial nephritis can also be present with primary glomerular diseases as well as systemic diseases affecting the kidney.

ACUTE TUBULOINTERSTITIAL NEPHRITIS

Pathogenesis and Pathology

The hallmarks of acute TIN are lymphocytic infiltration of the tubulointerstitium, tubular edema, and varying degrees of tubular damage. Eosinophils may be present, particularly in drug-induced TIN; occasionally, granulomas occur. The pathogenesis is not fully understood, but a T-cell–mediated immune mechanism has been postulated. A large number of medications, especially antimicrobials, anticonvulsants, and analgesics, have been implicated as etiologic agents (Table 532-1). Other causes include infections, primary glomerular diseases, and systemic diseases such as systemic lupus erythematosus.

	Idiopathic

Clinical Manifestations

The classic presentation of acute TIN is fever, rash, and arthralgia in the setting of a rising serum creatinine. Although the full triad may be noted in drug-induced TIN, many patients with acute TIN do not demonstrate all of the typical features. The rash can vary from maculopapular to urticarial and is often transient. Patients often have nonspecific constitutional symptoms of nausea, vomiting, fatigue, and weight loss. Flank pain may be present, presumably secondary to stretching of the renal capsule from acute inflammatory enlargement of the kidney. If acute TIN is caused by a systemic disease such as systemic lupus erythematosus, the clinical presentation will be consistent with specific signs and symptoms of the underlying disease. Unlike the typical presentation of oliguric acute renal failure seen with glomerular diseases, 30-40% of patients with acute TIN are nonoliguric, and hypertension is less common. Peripheral eosinophilia can occur, especially with drug-induced TIN. Some degree of microscopic hematuria is invariably present, but significant hematuria or proteinuria >1.5 g/day is uncommon. One exception is patients whose TIN is caused by nonsteroidal antiinflammatory drugs (NSAIDs), who can present with the nephrotic syndrome. Urinalysis can reveal white blood cell, granular, or hyaline casts, but red blood cell casts (a characteristic of glomerular disease) are absent. The presence of urine eosinophils is neither sensitive nor specific. *Because of pyuria, the initial diagnosis may be a urinary tract infection.*

Diagnosis

The diagnosis is usually based on clinical presentation and laboratory findings. A renal biopsy will establish the correct diagnosis in cases where the etiology or clinical course confounds the diagnosis. A careful history of the timing of disease onset in relation to drug exposure is essential in suspected drug-induced TIN. Because of the immune-mediated nature of TIN, signs or symptoms generally appear

within 1-2 wk following exposure. In children, antimicrobials are a common inciting agent. NSAIDs are an important cause of acute TIN in children, and volume depletion or underlying chronic renal disease can increase the risk of occurrence. Urinalysis and serial measurements of serum creatinine and electrolytes should be monitored. Renal ultrasonography is not diagnostic but can demonstrate enlarged, echogenic kidneys. Removal of a suspected offending agent followed by spontaneous improvement in renal function is highly suggestive of the diagnosis, and additional testing is generally not performed in this setting. In more severe cases, in which the cause is unclear or the patient's renal function deteriorates rapidly, a renal biopsy is indicated.

Treatment and Prognosis

Treatment includes supportive care directed at addressing complications of acute renal failure such as hyperkalemia or volume overload (see Chapter 535.1). Corticosteroid administration within 2 wk of the discontinuation of certain offending agents (e.g., NSAIDs or antibiotics) can hasten recovery and improve the long-term prognosis in drug-induced TIN. Whether such therapy is indicated in other causes on TIN is not clear. For patients with prolonged renal insufficiency, the prognosis remains guarded, and severe acute TIN from any cause can progress to chronic TIN.

CHRONIC TUBULOINTERSTITIAL NEPHRITIS

In children, chronic TIN most commonly occurs in the context of (1) an underlying congenital urologic renal disease, such as obstructive uropathy or vesicoureteral reflux, or (2) an underlying metabolic disorder affecting the kidneys (see Table 532-1) Chronic TIN can occur as an idiopathic disease, although this is more common in adults.

The juvenile nephronophthisis (JN)–medullary cystic kidney disease complex (MCKD) is a group of inherited, genetically determined cystic renal diseases that share the common histologic finding of chronic TIN. At least 15 different genes are associated with JN, usually inherited as an autosomal recessive disease. These genes only define 30% of cases, and new genes are being identified at a rapid pace. Although uncommon in the United States, JN causes 10-20% of pediatric end-stage renal disease (ESRD) in Europe. Patients with JN typically present with polyuria, growth failure, unexplained anemia, and chronic renal failure in late childhood or adolescence. As a ciliopathy, JN is often associated with extrarenal features such as retinal degeneration, hepatobiliary disease, cerebellar vermis hypoplasia, laterality defects, intellectual disability, and shortening of bones. These features are represented in a number of syndromes, such as **Senior-Løken syndrome (retinitis pigmentosa), Joubert syndrome (cerebellar vermis hypoplasia), Bardet-Biedel syndrome (intellectual disability, obesity),** and **Jeune asphyxiating thoracic dystrophy** (**shortening of the long bones, narrow rib cage),** and many others. **MCKD** is an autosomal dominant disease that typically manifests in adulthood. **TIN with uveitis** is a rare autoimmune syndrome of chronic TIN with anterior uveitis and bone marrow granulomas that occurs primarily in adolescent girls. Chronic TIN is seen in all forms of progressive renal disease, regardless of the underlying cause, and the severity of interstitial disease is the single most important factor predicting progression to ESRD.

Pathogenesis and Pathology

The pathophysiology of chronic TIN is undefined, but data suggest that, in addition to abnormal cilia structure and function in JN and MCKD, it is immune mediated. Cells making up the interstitial infiltrate appear to be a combination of native interstitial cells, inflammatory cells recruited from the circulation, and resident tubular cells that undergo epithelial-mesenchymal transformation. Grossly, kidneys can appear pale and small for age. Microscopically, tubular atrophy and "dropout" with interstitial fibrosis and a patchy lymphocytic interstitial inflammation are seen. Patients with JN often have characteristic small cysts in the corticomedullary region. In primary chronic TIN, glomeruli are relatively spared until late in the disease course. Patients with chronic TIN secondary to a primary glomerular disease have histologic evidence of the primary disease.

Clinical Manifestations

The clinical features of chronic TIN are often nonspecific and can reflect signs and symptoms of chronic renal insufficiency (see Chapter 535). Fatigue, growth failure, polyuria, polydipsia, and enuresis are often present. Anemia that is seemingly disproportionate to the degree of renal insufficiency is common and is a particularly prominent feature in JN. Because tubular damage often leads to renal salt wasting, significant hypertension is unusual. Fanconi syndrome, proximal renal tubular acidosis, distal renal tubular acidosis, and hyperkalemic distal renal tubular acidosis can occur.

Diagnosis

The diagnosis is suggested by signs or symptoms of renal tubular damage such as polyuria and an elevated serum creatinine value, coupled with a history suggestive of a chronic disease, such as long-standing enuresis or the presence of anemia resistant to iron therapy. Radiographic studies, in particular ultrasonography, can give additional evidence of chronicity, such as small, echogenic kidneys, corticomedullary microcysts suggesting JN, or findings of obstructive uropathy. A vesicocystourethrogram can demonstrate the presence of vesicoureteral reflux or bladder abnormalities. If JN is suspected, molecular diagnosis is available. In instances in which the cause is unclear, a renal biopsy may be performed. In cases of advanced disease, a renal biopsy might not be diagnostic. Many end-stage kidney diseases display a common histologic appearance of tubular fibrosis and inflammation.

Treatment and Prognosis

Therapy is directed at maintaining fluid and electrolyte balance and avoiding further exposure to nephrotoxic agents. Patients with obstructive uropathies can require salt supplementation and treatment with potassium-binding resin (Kayexalate). Prevention of infection by antibiotic prophylaxis can slow progression of renal damage in appropriate patients. Prognosis in patients with chronic TIN depends in large part on the nature of the underlying disease. Patients with obstructive uropathy or vesicoureteral reflux can have a variable degree of renal damage and thus a variable course. ESRD can develop over mo to years. Patients with JN uniformly progress to ESRD by adolescence. Patients with metabolic disorders can benefit from treatment when available.

Toxic Nephropathy

Craig C. Porter and Ellis D. Avner

Aberrant renal function often results from purposeful or accidental exposure to any number of agents that are potential or actual nephrotoxins. Iodinated radiocontrast agents are generally well tolerated by most patients without significant adverse consequences. In volume-depleted patients or patients with underlying chronic kidney

disease, their use poses a serious risk for the development of acute kidney injury with significant attendant morbidity and mortality. Biologic nephrotoxins include venomous exposures from insects, reptiles, amphibians, and a wide variety of sea-dwelling animals. The most common forms of toxic nephropathy unfortunately relate to the exposure of children to pharmacologic agents, accounting for close to 20% of episodes of acute kidney injury occurring in children and adolescents. Age, underlying medical condition, including surgical exposure, genetics, exposure dose, and the concomitant use of other drugs all influence the likelihood of developing acute kidney injury.

Table 533-1 summarizes the agents that commonly cause acute kidney injury and some of their clinical manifestations. Mechanisms

of injury often help to explain the presentation; multiple toxic exposures in patients with complicated clinical histories often limit the ability to clearly establish clinical cause and effect. For example, diminished urine output may be the clinical hallmark of tubular obstruction caused by agents such as methotrexate or agents that cause acute tubular necrosis, such as amphotericin B or pentamidine. Alternatively, nephrogenic diabetes insipidus may be the critical clinical manifestation of agents that cause interstitial nephritis, such as lithium or cisplatin. Nephrotoxicity is often reversible if the noxious agent is promptly removed.

Clinical use of potential nephrotoxins should be used judiciously. Necessity of exposure, dosing parameters, and the use of drug levels or pharmacogenomic data, when available, should always be considered. Caution is particularly mandated for patients with complex medical conditions that include preexisting renal disease, cardiac disease, diabetes, and/or complicated surgeries. Alternative approaches to imaging, or use of different pharmacologic options should be considered when possible. Imaging modalities such as ultrasonography, radionuclide scanning, or magnetic resonance imaging may be preferable to contrast studies in some patients. Alternatively, judicious volume expansion with or without the administration of *N*-acetylcysteine might offer renoprotection when radioiodinated contrast studies are critical. Pharmacologic agents with no known renal effects can often be substituted for known nephrotoxins with equal clinical efficacy. In all cases, simultaneous use of known nephrotoxins should be avoided whenever necessary.

Chapter **534**

Cortical Necrosis

Priya Pais and Ellis D. Avner

Renal cortical necrosis is a rare cause of acute renal failure occurring secondary to extensive ischemic damage of the renal cortex. It occurs most commonly in neonates and in adolescents of childbearing age (see Chapter 535).

ETIOLOGY

In newborns, cortical necrosis is most commonly associated with hypoxic or ischemic insults caused by perinatal asphyxia, placental abruption, and twin–twin or fetal-maternal transfusion. Other causes include renal vascular thrombosis and severe congenital heart disease. After the neonatal period, cortical necrosis is most commonly seen in children with septic shock or severe hemolytic-uremic syndrome. In adolescents and women, cortical necrosis occurs in association with obstetric complications including prolonged intrauterine fetal death, placental abruption, or amniotic fluid embolism.

Less-common causes of cortical necrosis include malaria, extensive burns, snakebites, infectious endocarditis, and medications (e.g., nonsteroidal antiinflammatory agents). Acute renal cortical necrosis has also been reported to occur in systemic lupus erythematosus–associated antiphospholipid antibody syndrome.

CLINICAL MANIFESTATIONS

Cortical necrosis clinically presents as acute renal failure in patients with predisposing causes. Urine output is diminished and gross and/or microscopic hematuria may be present. Hypertension is common, and thrombocytopenia may be present as a result of renal microvascular injury.

LABORATORY AND RADIOLOGIC FINDINGS

Laboratory results are consistent with acute renal failure: an elevated blood urea nitrogen and creatinine, hyperkalemia, and metabolic acidosis. Anemia and thrombocytopenia are common. Urinalysis reveals hematuria and proteinuria.

Ultrasound examination with Doppler flow studies or CT scan demonstrates decreased perfusion to both kidneys. A radionuclide renal scan shows decreased uptake with significantly delayed or absent function.

TREATMENT

It is important to prevent or treat the underlying cause of acute cortical necrosis, when possible. Therapy involves medical management of acute renal failure, often with the initiation of dialysis as indicated. Management is otherwise supportive and involves volume repletion, correction of asphyxia, and treatment of sepsis.

PROGNOSIS

Untreated, renal cortical necrosis has a high mortality rate. Twenty to 40% of patients have partial recovery of renal function, the extent of which depends on the amount of preserved cortical tissue. All patients require long-term follow-up for chronic kidney disease.

Chapter 535
Renal Failure

535.1 Acute Kidney Injury

Rajasree Sreedharan and Ellis D. Avner

Acute kidney injury (AKI), formerly called acute renal failure, is a clinical syndrome in which a sudden deterioration in renal function results in the inability of the kidneys to maintain fluid and electrolyte homeostasis. AKI occurs in 2-3% of children admitted to pediatric tertiary care centers and in as many as 8% of infants in neonatal intensive care units. A classification system has been proposed to standardize the definition of AKI in adults. These criteria of **risk**, **injury**, **failure**, **loss**, and **end-stage renal disease** were given the acronym of RIFLE. A modified RIFLE criteria (pRIFLE) was developed to characterize the pattern of AKI in critically ill children (Table 535-1). Because RIFLE focuses on the glomerular filtration rate (GFR), a modification (Acute Kidney Injury Network) categorizes severity by rise in serum creatinine: stage 1 >150%, stage II >200%, stage III >300%.

PATHOGENESIS

AKI has been conventionally classified into 3 categories: prerenal, intrinsic renal, and postrenal (Table 535-2 and Fig. 535-1).

Table 535-1 Pediatric-Modified Rifle (pRIFLE) Criteria

CRITERIA	ESTIMATED CCL	URINE OUTPUT
Risk	eCCl decrease by 25%	<0.5 mL/kg/hr for 8 hr
Injury	eCCl decrease by 50%	<0.5 mL/kg/hr for 16 hr
Failure	eCCl decrease by 75% or eCCl <35 mL/min/1.73 m^2	<0.3 mL/kg/hr for 24 hr or anuric for 12 hr
Loss	Persistent failure >4 wk	
End-stage	End-stage renal disease (persistent failure >3 mo)	

CCl, creatinine clearance; eCCl, estimated creatinine clearance; pRIFLE, pediatric risk, injury, failure, loss, and end-stage renal disease.

Tumor
Urolithiasis
Hemorrhagic cystitis
Neurogenic bladder

Prerenal AKI, also called *prerenal azotemia,* is characterized by diminished effective circulating arterial volume, which leads to inadequate renal perfusion and a decreased GFR. Evidence of kidney damage is absent. Common causes of prerenal AKI include dehydration, sepsis, hemorrhage, severe hypoalbuminemia, and cardiac failure. If the underlying cause of the renal hypoperfusion is reversed promptly, renal function returns to normal. If hypoperfusion is sustained, intrinsic renal parenchymal damage can develop.

Intrinsic renal AKI includes a variety of disorders characterized by renal parenchymal damage, including sustained hypoperfusion and ischemia. Many forms of **glomerulonephritis,** including postinfectious glomerulonephritis, lupus nephritis, Henoch-Schönlein purpura nephritis, membranoproliferative glomerulonephritis, and anti–glomerular basement membrane nephritis, can cause AKI. Ischemic/hypoxic injury and nephrotoxic insults are the most common causes of intrinsic AKI in the United States, and are more common with an underlying comorbid condition; most are associated with cardiac, oncologic, urologic, renal, and genetic disorders or prematurity. Severe and prolonged ischemic/hypoxic injury and nephrotoxic insult lead to **acute tubular necrosis (ATN),** seen most often in critically ill infants and children. Mechanisms leading to ischemic AKI include hypotension/intravascular volume depletion (hemorrhage, third-space fluid losses, diarrhea), decreased effective intravascular volume (heart failure, cirrhosis, hepatorenal syndrome, peritonitis, abdominal compartment syndrome), vasodilation/vasoconstriction (sepsis, hepatorenal syndrome), renal artery obstruction (thrombosis, embolization, stenosis), intrarenal artery disease (vasculitis, hemolytic-uremic syndrome, sickle cell anemia, transplant rejection), and impaired renal blood flow (cyclosporine, tacrolimus, angiotensin-converting enzyme [ACE] inhibitors, angiotensin-receptor blocking agents, radiocontrast agents).

The typical pathologic feature of ATN is tubular cell necrosis, although significant histologic changes are not consistently seen in patients with clinical ATN. The mechanisms of injury in ATN can include alterations in intrarenal hemodynamics, tubular obstruction, and passive backleak of the glomerular filtrate across injured tubular cells into the peritubular capillaries.

Tumor lysis syndrome is a specific form of AKI related to spontaneous or chemotherapy-induced cell lysis in patients with lymphoproliferative malignancies. This disorder is primarily caused by obstruction of the tubules by uric acid crystals (see Chapters 495 and 496). **Acute interstitial nephritis** is another common cause of AKI and is usually a result of a hypersensitivity reaction to a therapeutic agent or various infectious agents (see Chapter 532).

Postrenal AKI includes a variety of disorders characterized by obstruction of the urinary tract. In neonates and infants, congenital conditions, such as posterior urethral valves and bilateral ureteropelvic junction obstruction, account for the majority of cases of AKI. Other conditions, such as urolithiasis, tumor (intraabdominal lesion or within the urinary tract), hemorrhagic cystitis, and neurogenic bladder, can cause AKI in older children and adolescents. In a patient with 2 functioning kidneys, obstruction must be bilateral to result in AKI. Relief of the obstruction usually results in recovery of renal function, except in patients with associated renal dysplasia or prolonged urinary tract obstruction.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A carefully taken history is critical in defining the cause of AKI. An infant with a 3 day history of vomiting and diarrhea most likely has prerenal AKI caused by volume depletion, but hemolytic-uremic syndrome (HUS) must be a consideration. A 6 yr old child with a recent pharyngitis who presents with periorbital edema, hypertension, and gross hematuria most likely has intrinsic AKI related to acute postinfectious glomerulonephritis. A critically ill child with a history of protracted hypotension or with exposure to nephrotoxic medications most likely has ATN. A neonate with a history of hydronephrosis on prenatal ultrasound and a palpable bladder most likely has congenital urinary tract obstruction, probably related to posterior urethral valves.

The physical examination must be thorough, with careful attention to volume status. Tachycardia, dry mucous membranes, and poor peripheral perfusion suggest an inadequate circulating volume and the possibility of prerenal AKI (see Chapter 57). Hypertension, peripheral edema, rales, and a cardiac gallop suggest volume overload and the possibility of intrinsic AKI from glomerulonephritis or ATN. The presence of a rash and arthritis might indicate systemic lupus erythematosus (SLE) or Henoch-Schönlein purpura nephritis. Palpable flank masses may be seen with renal vein thrombosis, tumors, cystic disease, or urinary tract obstruction.

LABORATORY FINDINGS

Laboratory abnormalities can include anemia (the anemia is usually dilutional or hemolytic, as in SLE, renal vein thrombosis,

Table 535-3 Urinalysis, Urine Chemistries, and Osmolality in Acute Kidney Injury

	HYPOVOLEMIA	ACUTE TUBULAR NECROSIS	ACUTE INTERSTITIAL NEPHRITIS	GLOMERULONEPHRITIS	OBSTRUCTION
Sediment	Bland	Broad, brownish granular casts	White blood cells, eosinophils, cellular casts	Red blood cells, red blood cell casts	Bland or bloody
Protein	None or low	None or low	Minimal but may be increased with NSAIDs	Increased, >100 mg/dL	Low
Urine sodium, mEq/L*	<20	>30	>30	<20	<20 (acute) >40 (few days)
Urine osmolality, mOsm/kg	>400	<350	<350	>400	<350
Fractional excretion of sodium %†	<1	>1	Varies	<1	<1 (acute) >1 (few days)

*The sensitivity and specificity of urine sodium of <20 mEq/L in differentiating prerenal azotemia from acute tubular necrosis are 90% and 82%, respectively.
†Fractional excretion of sodium is the urine:plasma (U:P) ratio of sodium divided by U:P of creatinine ×100. The sensitivity and specificity of fractional excretion of sodium of <1% in differentiating prerenal azotemia from acute tubular necrosis are 96% and 95%, respectively.
NSAIDs, nonsteroidal antiinflammatory drugs.
From Singri N, Ahya SN, Levin ML: Acute renal failure, JAMA *289:747–751, 2003.*

HUS); leukopenia (SLE, sepsis); thrombocytopenia (SLE, renal vein thrombosis, sepsis, HUS); hyponatremia (dilutional); metabolic acidosis; elevated serum concentrations of blood urea nitrogen, creatinine, uric acid, potassium, and phosphate (diminished renal function); and hypocalcemia (hyperphosphatemia).

The serum C3 level may be depressed (postinfectious glomerulonephritis, SLE, or membranoproliferative glomerulonephritis), and antibodies may be detected in the serum to streptococcal (poststreptococcal glomerulonephritis), nuclear (SLE), neutrophil cytoplasmic (granulomatosis with polyangiitis, microscopic polyarteritis), or glomerular basement membrane (Goodpasture disease) antigens.

The presence of hematuria, proteinuria, and red blood cell or granular urinary casts suggests intrinsic AKI, in particular glomerular disease and ATN. The presence of white blood cells and white blood cell casts with low-grade hematuria and proteinuria suggests tubulointerstitial disease. Urinary eosinophils may be present in children with drug-induced tubulointerstitial nephritis.

Urinary indices may be useful in differentiating prerenal AKI from intrinsic AKI (Table 535-3). Patients whose urine shows an elevated specific gravity (>1.020), elevated urine osmolality (UOsm > 500 mOsm/kg), low urine sodium (UNa < 20 mEq/L), and fractional excretion of sodium <1% (<2.5% in neonates) most likely have prerenal AKI. Those with a specific gravity of <1.010, low urine osmolality (UOsm < 350 mOsm/kg), high urine sodium (UNa > 40 mEq/L), and fractional excretion of sodium >2% (>10% in neonates) most likely have intrinsic AKI.

Chest radiography may reveal cardiomegaly, pulmonary congestion (fluid overload), or pleural effusions. Renal ultrasonography can reveal hydronephrosis and/or hydroureter, which suggest urinary tract obstruction, or nephromegaly, consistent with intrinsic renal disease. Renal biopsy can ultimately be required to determine the precise cause of AKI in patients who do not have clearly defined prerenal or postrenal AKI.

Although serum creatinine is used to measure kidney function, it is an insensitive and delayed measure of decreased kidney function following AKI. Other biomarkers under investigation include changes in plasma neutrophil gelatinase–associated lipocalin and cystatin C levels and urinary changes in neutrophil gelatinase-associated lipocalin, interleukin 18, and kidney injury molecule-1.

TREATMENT

Medical Management

In infants and children with urinary tract obstruction, such as in a newborn with suspected posterior ureteral valves, a bladder catheter should be placed immediately to ensure adequate drainage of the urinary tract. The placement of a bladder catheter may also be considered in nonambulatory older children and adolescents to accurately monitor urine output during AKI; however, precautions to prevent iatrogenic infection should be taken.

Determination of the volume status is of critical importance when initially evaluating a patient with AKI. If there is no evidence of volume overload or cardiac failure, intravascular volume should be expanded by intravenous administration of isotonic saline, 20 mL/kg over 30 min. In the absence of blood loss or hypoproteinemia, colloid-containing solutions are not required for volume expansion. Severe hypovolemia may require additional fluid boluses (see Chapters 56, 57, and 70). Determination of the central venous pressure may be helpful if adequacy of the blood volume is difficult to determine. After volume resuscitation, hypovolemic patients generally void within 2 hr; failure to do so suggests intrinsic or postrenal AKI. Hypotension caused by sepsis requires vigorous fluid resuscitation followed by a continuous infusion of norepinephrine.

Diuretic therapy should be considered only after the adequacy of the circulating blood volume has been established. Furosemide (2-4 mg/kg) and mannitol (0.5 g/kg) may be administered as a single IV dose. Bumetanide (0.1 mg/kg) may be given as an alternative to furosemide. If urine output is not improved, then a continuous diuretic infusion may be considered. To increase renal cortical blood flow, many clinicians administer dopamine (2-3 µg/kg/min) in conjunction with diuretic therapy, although no controlled data support this practice. There is little evidence that diuretics or dopamine can prevent AKI or hasten recovery. Mannitol may be effective in prevention of pigment (myoglobin, hemoglobin)-induced renal failure. Atrial natriuretic peptide may be of value in preventing or treating AKI, although there is little pediatric evidence to support its use.

If there is no response to a diuretic challenge, diuretics should be discontinued and fluid restriction is essential. Patients with a relatively normal intravascular volume should initially be limited to 400 mL/m^2/24 hr (insensible losses) plus an amount of fluid equal to the urine output for that day. Extrarenal (blood, gastrointestinal tract) fluid losses should be replaced, milliliter for milliliter, with appropriate fluids. Markedly hypervolemic patients can require further fluid restriction, omitting the replacement of insensible fluid losses, urine output, and extrarenal losses to diminish the expanded intravascular volume. Fluid intake, urine and stool output, body weight, and serum chemistries should be monitored on a daily basis.

In AKI, rapid development of **hyperkalemia** (serum potassium level > 6 mEq/L) can lead to cardiac arrhythmia, cardiac arrest, and death. The earliest electrocardiographic change seen in patients with developing hyperkalemia is the appearance of peaked T waves. This may be followed by widening of the QRS intervals, ST segment depression, ventricular arrhythmias, and cardiac arrest (see Chapter 55.4).

Procedures to deplete body potassium stores should be initiated when the serum potassium value rises to >6.0 mEq/L. Exogenous sources of potassium (dietary, intravenous fluids, total parenteral nutrition) should be eliminated. Sodium polystyrene sulfonate resin (Kayexalate), 1 g/kg, should be given orally or by retention enema. This resin exchanges sodium for potassium and can take several hr to take effect. A single dose of 1 g/kg can be expected to lower the serum potassium level by about 1 mEq/L. Resin therapy may be repeated every 2 hr, the frequency being limited primarily by the risk of sodium overload.

More severe elevations in serum potassium (>7 mEq/L), especially if accompanied by electrocardiographic changes, require emergency measures in addition to Kayexalate. The following agents should be administered:

- Calcium gluconate 10% solution, 1.0 mL/kg IV, over 3-5 min
- Sodium bicarbonate, 1-2 mEq/kg IV, over 5-10 min
- Regular insulin, 0.1 units/kg, with glucose 50% solution, 1 mL/kg, over 1 hr

Calcium gluconate counteracts the potassium-induced increase in myocardial irritability but does not lower the serum potassium level. Administration of sodium bicarbonate, insulin, or glucose lowers the serum potassium level by shifting potassium from the extracellular to the intracellular compartment. A similar effect has been reported with the acute administration of β-adrenergic agonists in adults, but there are no controlled data in pediatric patients. Because the duration of action of these emergency measures is just a few hours, persistent hyperkalemia should be managed by dialysis.

Mild **metabolic acidosis** is common in AKI because of retention of hydrogen ions, phosphate, and sulfate, but it rarely requires treatment. If acidosis is severe (arterial pH < 7.15; serum bicarbonate < 8 mEq/L) or contributes to significant hyperkalemia, treatment is indicated. The acidosis should be corrected partially by the intravenous route, generally giving enough bicarbonate to raise the arterial pH to 7.20 (which approximates a serum bicarbonate level of 12 mEq/L). The remainder of the correction may be accomplished by oral administration of sodium bicarbonate after normalization of the serum calcium and phosphorus levels. Correction of metabolic acidosis with intravenous bicarbonate can precipitate tetany in patients with renal failure as rapid correction of acidosis reduces the ionized calcium concentration (see Chapter 55).

Hypocalcemia is primarily treated by lowering the serum phosphorus level. Calcium should not be given intravenously, except in cases of tetany, to avoid deposition of calcium salts into tissues. Patients should be instructed to follow a low-phosphorus diet, and phosphate binders should be orally administered to bind any ingested phosphate and increase GI phosphate excretion. Common agents include sevelamer (Renagel), calcium carbonate (Tums tablets or Titralac suspension), and calcium acetate (PhosLo). Aluminum-based binders, commonly employed in the past, should be avoided because of the risk of aluminum toxicity.

Hyponatremia is most commonly a dilutional disturbance that must be corrected by fluid restriction rather than sodium chloride administration. Administration of hypertonic (3%) saline should be limited to patients with symptomatic hyponatremia (seizures, lethargy) or those with a serum sodium level <120 mEq/L. Acute correction of the serum sodium to 125 mEq/L (mmol/L) should be accomplished using the following formula:

$$\text{mEq sodium required} = 0.6 \times \text{weight in kg} \times (125 - \text{serum sodium in mEq/L}).$$

AKI patients are predisposed to **GI bleeding** because of uremic platelet dysfunction, increased stress, and heparin exposure if treated with hemodialysis or continuous renal replacement therapy. Oral or intravenous H_2 blockers such as ranitidine are commonly administered to prevent this complication.

Hypertension can result from hyperreninemia associated with the primary disease process and/or expansion of the extracellular fluid volume and is most common in AKI patients with acute glomerulonephritis or HUS. Salt and water restriction is critical, and diuretic administration may be useful (see Chapter 445). Isradipine (0.05-0.15 mg/kg/dose, maximum dose 5 mg qid) may be administered for relatively rapid reduction in blood pressure. Longer-acting agents such as calcium channel blockers (amlodipine, 0.1-0.6 mg/kg/24 hr qd or divided bid) or β blockers (propranolol, 0.5-8.0 mg/kg/24 hr divided bid or tid; labetalol, 4-40 mg/kg/24 hr divided bid or tid) may be helpful in maintaining control of blood pressure. Children with severe symptomatic hypertension (hypertensive urgency or emergency) should be treated with continuous infusions of nicardipine (0.5-5.0 µg/kg/min), sodium nitroprusside (0.5-10.0 µg/kg/min), labetalol (0.25-3.0 mg/kg/hr), or esmolol (150-300 µg/kg/min) and converted to intermittently dosed antihypertensives when more stable.

Neurologic symptoms in AKI can include headache, seizures, lethargy, and confusion (encephalopathy). Potential etiologic factors include hypertensive encephalopathy, hyponatremia, hypocalcemia, cerebral hemorrhage, cerebral vasculitis, and the uremic state. Benzodiazepams are the most effective agents in acutely controlling seizures, and subsequent therapy should be directed toward the precipitating cause.

The **anemia** of AKI is generally mild (hemoglobin 9-10 g/dL) and primarily results from volume expansion (hemodilution). Children with HUS, SLE, active bleeding, or prolonged AKI can require transfusion of packed red blood cells if their hemoglobin level falls below 7 g/dL. In hypervolemic patients, blood transfusion carries the risk of further volume expansion, which can precipitate hypertension, heart failure, and pulmonary edema. Slow (4-6 hr) transfusion with packed red blood cells (10 mL/kg) diminishes the risk of hypervolemia. The use of fresh, washed red blood cells minimizes the acute risk of hyperkalemia, and the chronic risk of sensitization if the patient becomes a future candidate for renal replacement therapy. In the presence of severe hypervolemia or hyperkalemia, blood transfusions are most safely administered during dialysis or ultrafiltration.

Nutrition is of critical importance in children who develop AKI. In most cases, sodium, potassium, and phosphorus should be restricted. Protein intake should be moderately restricted while maximizing caloric intake to minimize the accumulation of nitrogenous wastes. In critically ill patients with AKI, parenteral hyperalimentation with essential amino acids should be considered.

Dialysis

Indications for dialysis in AKI include the following:

- Anuria/oliguria
- Volume overload with evidence of hypertension and/or pulmonary edema refractory to diuretic therapy
- Persistent hyperkalemia
- Severe metabolic acidosis unresponsive to medical management
- Uremia (encephalopathy, pericarditis, neuropathy)
- Blood urea nitrogen >100-150 mg/dL (or lower if rapidly rising)
- Calcium:phosphorus imbalance, with hypocalcemic tetany that cannot be controlled by other measures

An additional indication for dialysis is the inability to provide adequate nutritional intake because of the need for severe fluid restriction. In patients with AKI, dialysis support may be necessary for days or for up to 12 wk. Many patients with AKI require dialysis support for 1-3 wk. Table 535-4 lists the advantages and disadvantages of the 3 types of dialysis.

Intermittent hemodialysis is useful in patients with relatively stable hemodynamic status. This highly efficient process accomplishes both fluid and electrolyte removal in 3-4 hr sessions using a pump-driven extracorporeal circuit and large central venous catheter. Intermittent hemodialysis may be performed 3-7 times per week based on the patient's fluid and electrolyte balance.

Peritoneal dialysis is most commonly employed in neonates and infants with AKI, although this modality may be used in children and adolescents of all ages. Hyperosmolar dialysate is infused into the peritoneal cavity via a surgically or percutaneously placed peritoneal dialysis catheter. The fluid is allowed to dwell for 45-60 min and is then drained from the patient by gravity (manually or with the use of machine-driven cycling), accomplishing fluid and electrolyte removal. Cycles are repeated for 8-24 hr/day based on the patient's

fluid and electrolyte balance. Anticoagulation is not necessary. Peritoneal dialysis is contraindicated in patients with significant abdominal pathology.

Continuous renal replacement therapy (CRRT) is useful in patients with unstable hemodynamic status, concomitant sepsis, or multiorgan failure in the intensive care setting. CRRT is an extracorporeal therapy in which fluid, electrolytes, and small- and medium-size solutes are continuously removed from the blood (24 hr/day) using a specialized pump-driven machine. Usually, a double-lumen catheter is placed into the subclavian, internal jugular, or femoral vein. The patient is then connected to the pump-driven CRRT circuit, which continuously passes the patient's blood across a highly permeable filter.

CRRT may be performed in 3 basic fashions. In continuous venovenous hemofiltration, a large volume of fluid is driven by systemic or pump-assisted pressure across the filter, bringing with it by convection other molecules such as urea, creatinine, phosphorus, and uric acid. The blood volume is reconstituted by IV infusion of a replacement fluid having a desirable electrolyte composition similar to that of blood. Continuous venovenous hemofiltration dialysis uses the principle of diffusion by circulating dialysate in a countercurrent direction on the ultrafiltrate side of the membrane. No replacement fluid is used. Continuous hemodiafiltration employs both replacement fluid and dialysate, offering the most effective solute removal of all forms of CRRT.

Table 535-4 compares the relative risks and benefits of the various renal replacement therapies.

PROGNOSIS

The mortality rate in children with AKI is variable and depends entirely on the nature of the underlying disease process rather than on the renal failure itself. Children with AKI caused by a renal-limited condition such as postinfectious glomerulonephritis have a very low mortality rate (<1%); those with AKI related to multiorgan failure have a very high mortality rate (>90%).

The prognosis for recovery of renal function depends on the disorder that precipitated AKI. Recovery of renal function is likely after AKI resulting from prerenal causes ATN, acute interstitial nephritis, or tumor lysis syndrome. Recovery of renal function is unusual when AKI results from most types of rapidly progressive glomerulonephritis, bilateral renal vein thrombosis, or bilateral cortical necrosis. Medical management may be necessary for a prolonged period to treat the sequelae of AKI, including chronic renal insufficiency, hypertension, renal tubular acidosis, and urinary concentrating defect.

535.2 Chronic Kidney Disease

Rajasree Sreedharan and Ellis D. Avner

Chronic kidney disease (CKD) is determined by the presence of kidney damage and level of kidney function (GFR), irrespective of diagnosis. The stage of the CKD is assigned based on the level of kidney function (Tables 535-5 and 535-6). The prevalence of CKD in the pediatric population is approximately 18 per 1 million. The prognosis for the infant, child, or adolescent with CKD has improved dramatically since the 1970s because of improvements in medical management (aggressive nutritional support, recombinant erythropoietin, recombinant growth hormone), dialysis techniques, and kidney transplantation.

ETIOLOGY

In children, CKD may be the result of congenital, acquired, inherited, or metabolic renal disease, and the underlying cause correlates closely with the age of the patient at the time when CKD is first detected. CKD in children <5 yr old is most commonly a result of congenital abnormalities such as renal hypoplasia, dysplasia, or obstructive uropathy. Additional causes include congenital nephrotic syndrome, prune belly syndrome, cortical necrosis, focal segmental glomerulosclerosis, autosomal recessive polycystic kidney disease, renal vein thrombosis, and HUS.

After 5 yr of age, acquired diseases (various forms of glomerulonephritis including lupus nephritis) and inherited disorders (familial

Table 535-5 Criteria for Definition of Chronic Kidney Disease (NKF KDOQI Guidelines)

Patient has CKD if either of the following criteria are present:
1. Kidney damage for ≥3 mo, as defined by structural or functional abnormalities of the kidney, with or without decreased GFR, manifested by 1 or more of the following features:
   - Abnormalities in the composition of the blood or urine
   - Abnormalities in imaging tests
   - Abnormalities on kidney biopsy
2. GFR <60 mL/min/1.73 m^2 for ≥3 mo, with or without the other signs of kidney damage described above

NKF KDOQI, National Kidney Foundation Kidney Disease Outcomes Quality Initiative.

Table 535-6 Standardized Terminology for Stages of Chronic Kidney Disease (NKF KDOQI Guidelines)

STAGE	DESCRIPTION	GFR (mL/min/1.73 m^2)
1	Kidney damage with normal or increased GFR	>90
2	Kidney damage with mild decrease in GFR	60-89
3	Moderate decrease in GFR	30-59
4	Severe decrease in GFR	5-29
5	Kidney failure	<15 or on dialysis

GFR, glomerular filtration rate; NKF KDOQI, National Kidney Foundation Kidney Disease Outcomes Quality Initiative.

juvenile nephronophthisis, Alport syndrome) predominate. CKD related to metabolic disorders (cystinosis, hyperoxaluria) and certain inherited disorders (both autosomal dominant and recessive polycystic kidney disease) can occur throughout the childhood years.

PATHOGENESIS

In addition to progressive injury with ongoing structural or metabolic genetic diseases, renal injury can progress despite removal of the original insult.

Hyperfiltration injury may be an important final common pathway of glomerular destruction, independent of the underlying cause of renal injury. As nephrons are lost, the remaining nephrons undergo structural and functional hypertrophy characterized by an increase in glomerular blood flow. The driving force for glomerular filtration is thereby increased in the surviving nephrons. Although this compensatory hyperfiltration temporarily preserves total renal function, it can cause progressive damage to the surviving glomeruli, possibly by a direct effect of the elevated hydrostatic pressure on the integrity of the capillary wall and/or the toxic effect of increased protein traffic across the capillary wall. Over time, as the population of sclerosed nephrons increases, the surviving nephrons suffer an increased excretory burden, resulting in a vicious cycle of increasing glomerular blood flow and hyperfiltration injury.

Proteinuria itself can contribute to renal functional decline. Proteins that traverse the glomerular capillary wall can exert a direct toxic effect on tubular cells and recruit monocytes and macrophages, enhancing the process of glomerular sclerosis and tubulointerstitial fibrosis. Uncontrolled **hypertension** can exacerbate disease progression by causing arteriolar nephrosclerosis and by increasing the hyperfiltration injury.

Hyperphosphatemia can increase progression of disease by leading to calcium phosphate deposition in the renal interstitium and blood vessels. Hyperlipidemia, a common condition in CKD patients, can adversely affect glomerular function through oxidant-mediated injury.

CKD may be viewed as a continuum of disease, with increasing biochemical and clinical manifestations as renal function deteriorates. Regardless of etiology, the progression of tubulointerstitial fibrosis is the primary determinant of progression of CKD. Table 535-7 outlines the pathophysiologic manifestations of CKD. End-stage renal disease (ESRD) is an administrative term in the United States; it is used to define all patients who are treated with dialysis or kidney transplantation. Patients with ESRD are a subset of the patients with stage 5 CKD.

Table 535-7 Pathophysiology of Chronic Kidney Disease

MANIFESTATION	MECHANISMS
Accumulation of nitrogenous waste products	Decrease in glomerular filtration rate
Acidosis	Decreased ammonia synthesis Impaired bicarbonate reabsorption Decreased net acid excretion
Sodium retention	Excessive renin production Oliguria
Sodium wasting	Solute diuresis Tubular damage
Urinary concentrating defect	Solute diuresis Tubular damage
Hyperkalemia	Decrease in glomerular filtration rate Metabolic acidosis Excessive potassium intake Hyporeninemic hypoaldosteronism
Renal osteodystrophy	Impaired renal production of 1,25-dihydroxycholecalciferol Hyperphosphatemia Hypocalcemia Secondary hyperparathyroidism
Growth retardation	Inadequate caloric intake Renal osteodystrophy Metabolic acidosis Anemia Growth hormone resistance
Anemia	Decreased erythropoietin production Iron deficiency Folate deficiency Vitamin B_{12} deficiency Decreased erythrocyte survival
Bleeding tendency	Defective platelet function
Infection	Defective granulocyte function Impaired cellular immune functions Indwelling dialysis catheters
Neurologic symptoms (fatigue, poor concentration, headache, drowsiness, memory loss, seizures, peripheral neuropathy)	Uremic factor(s) Aluminum toxicity Hypertension
Gastrointestinal symptoms (feeding intolerance, abdominal pain)	Gastroesophageal reflux Decreased gastrointestinal motility Serositis (uremia)
Hypertension	Volume overload Excessive renin production
Hyperlipidemia	Decreased plasma lipoprotein lipase activity
Pericarditis, cardiomyopathy	Uremic factor(s) Hypertension Fluid overload
Glucose intolerance	Tissue insulin resistance

CLINICAL MANIFESTATIONS

The clinical presentation of CKD is varied and depends on the underlying renal disease. Children and adolescents with CKD from chronic glomerulonephritis can present with edema, hypertension, hematuria, and proteinuria. Infants and children with congenital disorders such as renal dysplasia and obstructive uropathy can present in the neonatal period with failure to thrive, polyuria, dehydration, urinary tract infection, or overt renal insufficiency. Congenital kidney disease is diagnosed with prenatal ultrasonography in many infants, allowing early diagnostic and possible therapeutic intervention. Children with familial juvenile nephronophthisis can have a very subtle presentation with nonspecific complaints such as headache, fatigue, lethargy, anorexia, vomiting, polydipsia, polyuria, and growth failure over a number of years.

The physical examination in patients with CKD can reveal pallor and a sallow appearance. Patients with long-standing untreated CKD can have short stature and the bony abnormalities of renal osteodystrophy (see Chapter 529.4). Children with CKD caused by chronic glomerulonephritis (or children with advanced renal failure from any cause) can have edema, hypertension, and other signs of extracellular fluid volume overload.

LABORATORY FINDINGS

Laboratory findings can include elevations in blood urea nitrogen and serum creatinine and can reveal hyperkalemia, hyponatremia (if volume overloaded), hypernatremia (loss of free water), acidosis, hypocalcemia, hyperphosphatemia, and an elevation in uric acid. Patients with heavy proteinuria can have hypoalbuminemia. A complete blood cell count may show a normochromic, normocytic anemia. Serum cholesterol and triglyceride levels are often elevated. In children with CKD caused by glomerulonephritis, the urinalysis shows hematuria and proteinuria. In children with CKD from congenital lesions

such as renal dysplasia, the urinalysis usually has a low specific gravity and minimal abnormalities by dipstick or microscopy.

Inulin clearance is the gold standard to determine GFR, but it is not easy to measure. Endogenous creatinine clearance is the most widely used marker of GFR, but creatinine secretion falsely elevates the calculated GFR. Several other markers are under investigation to accurately determine GFR in children, such as cystatin C and iohexol. In children age 1-16 yr, the degree of renal dysfunction may be determined by applying a new bedside formula that estimates GFR between 15 and 75 mL/min/1.73 m^2: estimated GFR = 0.43 × height in cm/serum creatinine in mg/dL

TREATMENT

The treatment of CKD is aimed at replacing absent or diminished renal functions, which progressively deteriorate in parallel with the progressive loss of GFR, and slowing the progression of renal dysfunction. Children with CKD should be treated at a pediatric center capable of supplying multidisciplinary services, including medical, nursing, social service, nutritional, and psychological support.

The management of CKD requires close monitoring of a patient's clinical and laboratory status. Blood studies to be followed routinely include serum electrolytes, blood urea nitrogen, creatinine, calcium, phosphorus, albumin, alkaline phosphatase, and hemoglobin levels. Periodic measurement of intact parathyroid hormone (PTH) levels and roentgenographic studies of bone may be of value in detecting early evidence of renal osteodystrophy. Echocardiography should be performed periodically to identify left ventricular hypertrophy and cardiac dysfunction that can occur as a consequence of the complications of CKD.

Nutrition

Nutritional management by a dietician experienced in pediatric renal patients is recommended by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI). Counseling based on individualized assessment should be considered for all children and their families with CKD stages 2 to 5 and 5D. Patients should receive 100% of estimated energy requirement for age, individually adjusted for physical activity level, body mass index, and response in rate of weight gain or loss. When oral supplemental nutrition with increased calories or fluid volume is insufficient, tube feeding should be considered. Calories should be balanced between carbohydrate, unsaturated fat in physiological ranges (per dietary reference intake [DRI]), and protein. Protein intake recommendation is 100-140% of the DRI for ideal weight for children with stage 3 CKD, 100-120% of the DRI in stages 4 and 5 CKD, and 100% with allowance for dialysis loss in CKD stage 5D, with use of commercial supplements as needed. Children with CKD stages 2-5 should receive 100% of DRI of vitamins and trace elements; water-soluble vitamin supplements are often required in CKD stage 5D.

Renal Osteodystrophy

The term *renal osteodystrophy* is used to indicate a spectrum of bone disorders seen in patients with CKD. The most common condition seen in children is high-turnover bone disease caused by secondary hyperparathyroidism. The skeletal pathologic finding in this condition is osteitis fibrosa cystica.

The **pathophysiology** of renal osteodystrophy is complex. Early in the course of CKD, when the GFR declines to approximately 50% of normal, the decrease in functional kidney mass leads to a decline in renal 1α-hydroxylase activity, with decreased production of activated vitamin D (1,25-dihydroxycholecalciferol). This deficiency in activated vitamin D results in decreased intestinal calcium absorption, hypocalcemia, and increased parathyroid gland activity. Excessive PTH secretion attempts to correct the hypocalcemia by increasing bone resorption. Later in the course of CKD, when the GFR declines to 20-25% of normal, compensatory mechanisms that have been operative to enhance renal phosphate excretion become inadequate, resulting in hyperphosphatemia, which further promotes hypocalcemia and increased PTH secretion.

Clinical manifestations of renal osteodystrophy include muscle weakness, bone pain, and fractures with minor trauma. In growing children, rachitic changes, varus and valgus deformities of the long bones, and slipped capital femoral epiphyses may be seen. Laboratory studies can demonstrate a decreased serum calcium level and increased serum phosphorus, alkaline phosphatase, and PTH levels. Radiographs of the hands, wrists, and knees show subperiosteal resorption of bone with widening of the metaphyses.

The goals of **treatment** are to prevent bone deformity and normalize growth velocity using both dietary and pharmacologic interventions. The target phosphorus level for adolescents is between 3.5 and 5.5 mg/dL, and for children 1-12 yr of age it is 4-6 mg/dL. Children and adolescents should follow a low-phosphorus diet, and infants should be provided with a low-phosphorus formula such as Similac PM 60/40. It is impossible to fully restrict phosphorus intake, and so phosphate binders are used to enhance GI phosphate excretion. Although calcium-based binders have historically been the most commonly used, non–calcium-based binders such as sevelamer (Renagel) are increasing in use, particularly in older children and adolescent patients who are prone to hypercalcemia. Because aluminum may be absorbed from the GI tract and can lead to aluminum toxicity, aluminum-based binders should be avoided.

The cornerstone of therapy for renal osteodystrophy is vitamin D administration. **Vitamin D therapy** is indicated in patients with 1,25-dihydroxy-vitamin D levels below the established goal range for the child's particular stage of CKD or in patients with PTH levels above the established goal range for CKD stage. Patients with low 1,25-dihydroxy-vitamin D and elevated PTH levels should be treated with 0.01-0.05 µg/kg/24 hr of calcitriol (Rocaltrol, 0.25-µg capsules or 1 µg/mL suspension). Newer activated vitamin D analogs such as paricalcitol and doxercalciferol are increasingly used, especially in patients who are predisposed to hypercalcemia. Phosphate binders and vitamin D should be adjusted to maintain the PTH level within the designated goal range and the serum calcium and phosphorus levels within the normal range for age. Many nephrologists also attempt to maintain the calcium/phosphorus product ($Ca \times PO_4$) at <55 mg^2/dL^2 in adolescents and <65 mg^2/dL^2 in younger children to minimize the possibility of tissue deposition of calcium phosphorus salts with consequent damage.

Adynamic Bone Disease

Adynamic bone disease (low-turnover bone disease) has been recognized in children and adults with CKD. The pathologic finding is osteomalacia and is associated with oversuppression of PTH, perhaps related to the widespread use of calcium-containing phosphate binders and vitamin D analogs.

Fluid and Electrolyte Management

Most children with CKD maintain normal sodium and water balance, with the sodium intake derived from an appropriate diet. Infants and children whose CKD is a consequence of renal dysplasia may be polyuric, with significant urinary sodium or free water losses. These children may benefit from high-volume, low-caloric-density feedings with sodium supplementation. Children with high blood pressure, edema, or heart failure may require sodium restriction and diuretic therapy. Fluid restriction is rarely necessary in children with CKD until the development of ESRD requires the initiation of dialysis.

In most children with CKD, potassium balance is maintained until renal function deteriorates to the level at which dialysis is initiated. Hyperkalemia can develop, however, in patients with moderate renal insufficiency who have excessive dietary potassium intake, severe acidosis, or hyporeninemic hypoaldosteronism (related to destruction of the renin-secreting juxtaglomerular apparatus). Hyperkalemia may be treated by restriction of dietary potassium intake, administration of oral alkalinizing agents, and/or treatment with Kayexalate.

Acidosis

Metabolic acidosis develops in almost all children with CKD as a result of decreased net acid excretion by the failing kidneys. Either Bicitra

(1 mEq sodium citrate/mL) or sodium bicarbonate tablets (650 mg = 8 mEq of base) may be used to maintain the serum bicarbonate level >22 mEq/L.

Growth

Short stature is a significant long-term sequela of childhood CKD. Children with CKD have an apparent growth hormone–resistant state, with elevated growth hormone levels but decreased insulin-like growth factor 1 levels and major abnormalities of insulin-like growth factor–binding proteins.

Children with CKD who remain less than −2 SD for height despite optimal medical support (adequate caloric intake and effective treatment of renal osteodystrophy, anemia, and metabolic acidosis) might benefit from treatment with pharmacologic doses of recombinant human growth hormone (rHuGH). Treatment may be initiated with rHuGH (0.05 mg/kg/24 hr) subcutaneously, with periodic adjustment in the dose to achieve a goal of normal height velocity for age.

Treatment with rHuGH continues until the patient reaches the 50th percentile for midparental height, achieves a final adult height, or undergoes kidney transplantation. Long-term rHuGH treatment significantly improves final adult height and induces persistent catch-up growth; some patients achieve normal adult height.

Anemia

Anemia in patients with CKD is primarily the result of inadequate erythropoietin production by the failing kidneys and usually becomes manifest in patients with stages 3-4 CKD.

Other possible contributory factors include iron deficiency, folic acid or vitamin B_{12} deficiency, and decreased erythrocyte survival. Recombinant human erythropoietin (rHuEPO) therapy has decreased the need for transfusion in patients with CKD. Erythropoietin is usually initiated when the patient's hemoglobin concentration falls below 10 g/dL, at a dose of 50-150 mg/kg/dose subcutaneously 1-3 times weekly. The dose is adjusted to maintain the hemoglobin concentration between 11 and 12 g/dL. All patients receiving rHuEPO therapy should be provided with either oral or intravenous iron supplementation. Patients who appear to be resistant to rHuEPO should be evaluated for iron deficiency, occult blood loss, a chronic infection or inflammatory state, vitamin B_{12} or folate deficiency, or bone marrow fibrosis related to secondary hyperparathyroidism. An alternative option to rHuEPO is darbepoetin alfa (Aranesp), a longer-acting agent administered at a dose of 0.45 µg/kg/wk. The chief advantage of this agent is that it may be dosed once weekly to once monthly because of its extended duration of action.

Hypertension

Children with CKD can have sustained hypertension related to volume overload and/or excessive renin production related to glomerular disease. Hypertensive children with suspected volume overload should follow a salt-restricted diet (<2 g/24 hr) and may benefit from diuretic therapy. Thiazide diuretics (hydrochlorothiazide 2 mg/kg/24 hr divided bid) are the initial diuretic class of choice for children with mild renal dysfunction (CKD stages 1-3). However, when a patient's estimated GFR falls below this range, thiazides are ineffective and loop diuretics (furosemide 1-2 mg/kg/dose bid or tid) become the diuretic class of choice. **ACE inhibitors** (enalapril, lisinopril) and **angiotensin II receptor blockers** (losartan) are the antihypertensive medications of choice in all children with proteinuric renal disease because of their potential ability to decrease proteinuria and slow the progression to ESRD (by mechanisms still not completely delineated). Extreme care must be used with these agents, however, to monitor renal function and electrolyte balance, particularly in children with advanced CKD. Calcium channel blockers (amlodipine), β-blockers (propranolol, atenolol), and centrally acting agents (clonidine) may be useful as adjunctive agents in children with CKD whose blood pressure cannot be controlled using dietary sodium restriction, diuretics, and ACE inhibitors.

Immunizations

Children with CKD should receive all standard immunizations according to the schedule used for healthy children. An exception must be made in withholding live virus vaccines from children with CKD related to glomerulonephritis, or any disease, during treatment with immunosuppressive medications. It is critical, however, to make every attempt to administer live virus vaccines for measles, mumps, rubella, and varicella before kidney transplantation. These vaccines are not advised for use in immunosuppressed patients. All children with CKD should receive a yearly influenza vaccine. Data from a number of studies suggest that children with CKD might respond suboptimally to immunizations.

Adjustment In Drug Dose

Because many drugs are excreted by the kidneys, their dosing might need to be adjusted in patients with CKD to maximize effectiveness and minimize the risk of toxicity. Strategies in dosage adjustment include lengthening of the interval between doses or decreasing the absolute dose, or both. Such adjustments become even more important as pharmacogenomic profiling of drug metabolism becomes routine.

Progression of Disease

Although there are no definitive treatments to improve renal function in children or adults with CKD other than treatment of a specific underlying disorder when possible, there are several general strategies that may be effective in slowing the rate of progression of renal dysfunction. Optimal control of hypertension (maintaining the blood pressure at lower than the 75th percentile and perhaps even lower) is critical in all patients with CKD. ACE inhibitors or angiotensin II receptor blockers should be the antihypertensive drugs of choice in hypertensive children with chronic proteinuric renal disease as previously noted. Such agents should also be strongly considered in children with CKD who have significant proteinuria, even in the absence of hypertension, although there are no controlled studies to support this approach. Serum phosphorus should be maintained within the normal range for age and the calcium–phosphorus product <55 to minimize renal calcium–phosphorus deposition. Prompt treatment of infectious complications and episodes of dehydration can minimize additional loss of renal parenchyma.

Other potentially beneficial recommendations include correction of anemia with erythropoietin or darbepoetin alfa therapy, control of hyperlipidemia, avoidance of cigarette smoking, prevention of obesity, and avoidance of nonsteroidal antiinflammatory and other potential nephrotoxic medications. This includes a variety of illegal street drugs as well as herbal and/or homeopathic medications or "supplements." Although dietary protein restriction may be useful in adults, this recommendation is generally not suggested for children with CKD because of the concern about adverse effects on growth and development.

Bibliography is available at Expert Consult.

535.3 End-Stage Renal Disease

Rajasree Sreedharan and Ellis D. Avner

ESRD represents the state in which a patient's renal dysfunction has progressed to the point at which homeostasis and survival can no longer be sustained with native kidney function and maximal medical management. At this point, renal replacement therapy (dialysis or renal transplantation) becomes necessary. The ultimate goal for children with ESRD is successful kidney transplantation (see Chapter 536)
